11 **Abstract**

12 The earthbag and superadobe techniques consist of introducing soil in degradable bags that are stacked to

13 form adobe structures. They represent sustainable, rapid and low-cost alternatives for the construction of

14 social housing, emergency shelter and ecovillages with the resources available at each location. Despite

15 their potential, several aspects still compromise the efficient and safe use of these techniques. For

16 instance, the design of the structures is currently based on empirical or semi-empirical guidelines since no

17 general method exists on the matter. The present work focuses on the proposal of simple, comprehensive

18 and rational design method for earthbag and superadobe walls and domes. Formulations are proposed

19 considering the previous studies from the literature. Parametric studies are conducted in order to evaluate

20 the influence of several geometrical and mechanical variables on the response and safety of the structures

21 built with this technique. The design method is then evaluated numerically through a finite element

22 analysis. The developments derived from this study represent a contribution towards the safe and

23 optimized design of earthbag and superadobe structures, being a valuable guide for future construction.

1. INTRODUCTION

In emergency situations (such as humanitarian crisis, wars or hazardous natural events) it is essential to provide the population affected with safe and secure shelter, quickly and at low costs. Among the possible materials for the construction of such shelters, the most abundant regardless of the location is the earth or soil available in the environment. In this context, the construction techniques of the earthbag and the superadobe were developed.

These techniques consist of introducing local soil and small amounts of a binder in degradable bags that serve as the formwork and as confinement of the filling. The bags are stacked one over the other forming the walls of the house. The earthbag technique uses regular bags to contain the soil, whereas the superadobe employs long bags as shown in Fig.1. The adherence and friction between rows is improved by placing barbwire on top of each row. Once the bags are filled, they are slightly compressed to remove the air inside the bag and to regularise the contact surface. This allows the construction of walls and domes, as shown in Fig. 1. The technique has been extensively applied in emergency situations in Africa and South America, showing benefits in terms of acoustic and thermal insulation properties (Teslik and Vodicková 2014, Zhao et al. 2015).

Fig. 1 - Construction of superadobe structures (sources: www.labioguia.com (a), www.domoterra.es (b, d), www.earthbagbuilding.com (c))

This construction technique has spread in the past 25 years since its creation by the Iranian architect Nader Khalili, who proposed fundamental rules for the design and building recommendations (Khalili 1986). Khalili was also the founder of Cal-Earth Institute in the United States (US) that promotes the development and research on earth structures. Experimental studies regarding structures under static and dynamic loads were conducted in order to evaluate the global stability and the earthquake response (Khalili and Vittore 1998). Based on the results obtained, the superadobe was recognized as a building technique in California with some restriction of the maximum dimensions of the structures. In the past 10 years, research has also been conducted on the compressive (Daigle 2008, Pelly 2010, Croft

75   2011) and shear (Vadgama 2010, Croft 2011) behaviour of earthbag piles or walls, providing

76   experimental data about the material and the structure.

77   Despite the advances attained, the design is still based on empirical or semi-empirical rules

78   (Minke 2001, Wojciechowska 2001, Hunter and Kiffmeyer 2004, Geiger 2011). Even though

79   several countries such as the US (ASTM 2010), Brazil (ABNT 1998) and Spain (AENOR 2008,

80   Cid et al. 2011) include the soil as a building material in the form of adobe or mud walls, the

81   earthbag technique (combined behaviour of the earth and the bag with joints) is not

82   contemplated in the standards due to the lack of theoretical models for the design of structures

83   and testing methods for the characterization of the material.

84   Generally, no structural analysis is conducted prior to building. In the cases that calculations are

85   performed, the design is restricted to the study of the roll-over stability and the collapse of the

86   superadobe under the hypothesis that the domes work monolithically. Cross-sections are

87   assumed capable of bearing tangential and normal (both compressive and tensile) stresses,

88   which is not completely true in the case of superadobe domes since joints between bags

89   introduce a special structural behavior. Moreover, geometric variations, material properties,

90   environmental conditions and other boundary conditions are hardly ever taken into account.

91   This scenario may lead to either an overestimated or an unsafe design of structures, which

92   contrasts with the sustainable philosophy grounded on the efficient use of the resources and raw

93   materials associated with the technique.

94   The objective of this study is to propose a simple, comprehensive and rational design method

95   for earthbag and superadobe structures that enables an efficient use of the resources and raw

96   materials available in the environment and ensures the construction of safe structures. The

97   simplicity is considered paramount here since the method should be easily implemented, even

98   without advanced computational tools that might not be available in extreme conditions or

99   isolated locations where the technique should be applied. The proposal of the design method is

100 made separately for the walls and for the domes, accounting for possible combinations between

101 them. Based on previous experimental and numerical studies from the literature, the main

102 failure and resistant mechanisms are first identified. A simplified procedure to verify the

103 resistant capacity of the earthbag walls and domes with safety margins is proposed. Then, the

104 influence of several geometric and mechanical variables on the structural response is ascertained

105 through a parametric study that allows determining critical parameters for the design. The

106 simplified method is also numerically validated by means of a finite element analysis and

107 compared with other alternative approaches from the literature.

108 The present study contributes to increase the knowledge on the earthbag and superadobe

109 techniques by presenting a first step towards a general design method valid for earthbag or

110 superadobe structures. The rational approach ensures the structural safety and the optimization

111 of the material, thus enhancing its sustainability and setting the basis for future design

112 recommendations or codes. Besides being a valuable guide from an engineering standpoint, this
113 study might have a positive social impact in emergency and humanitarian crisis situations.
114

115 **2. TYPICAL SUPERADOBE STRUCTURE**

116

117 Superadobe structures may present a rectangular plant with straight walls or a round plant with
118 walls that provide support to a dome. Walls are usually built with bags ranging from 0.30 to
119 0.40 m wide that are piled up to a height of 2.5 m. The dome is usually formed by piling
120 consecutive rows of bags with a perimeter that reduces with the height.
121 Fig. 2a shows a typical vertical cross section of a superadobe construction composed by dome,
122 wall, buttress and foundation. The buttress is an external containing wall used when high
123 horizontal forces are applied. The foundations provide support to the structure, consisting of a
124 minimum of 3 rows below the ground level that transmit the horizontal and vertical forces to the
125 ground. In case the properties of the soil do not meet the load requirements, the number of rows
126 in the foundations may be increased.

127

128
129 *Fig. 2 - Cross section of a dome house (a) conventional and superadobe domes differences (b)*

130

131 The inner diameter of the dome may range between 3.5 m and 5.0 m. In earthbag or superadobe
132 construction, it is possible to connect several domes with the aim of dividing the inner spaces as
133 shown in Fig. 2a. Moreover, openings are also introduced to generate place for doors and
134 windows. Wood, concrete or steel beams are installed above the openings to redirect the loads
135 around them since the earthbags do not provide enough stiffness at early stages.
136 Studies from the literature analysed different properties of the material (Lohani et al. 2006,
137 Daigle 2008, Pelly 2010, Vadgama 2010 and Croft 2011). In particular, Croft (2011) performed
138 laboratory tests of earthbag piles to evaluate the tensile strength (T_{bag}) and a tearing resistance
139 (T_{tear}) of the bag. Moreover, Vadgama (2010) conducted tests to evaluate the behaviour of the
140 earthbag joints with barbed wire between rows. The author demonstrates that the inclusion of
141 the barbed wire increases the cohesion (C_{bw}) and the static friction coefficient (μ_{bags}) of the

4

142 contact between bags. Although the properties depend on the characteristics of the bag and
143 adobe used, typical values reported by those authors are summarized in Table 1. Notice that no
144 value of the tensile yield stress of the adobe ($f_{adobe,\_t}$) is provided in the studies. This value is
145 generally assumed as 1% of the compressive yield stress of the adobe (f_{adobe}).

146

147   *Table 1 – Material properties*

Parameter	Value	Reference
T_{bag}	10 kN/m	Croft (2011)
T_{tear}	0.14 kN	Croft (2011)
C_{bw}	5.50 kN/m^2	Vadgama (2010)
μ_{bags}	0.67	Vadgama (2010)
f_{adobe}	2000 kN/m^2	Robin et al. (2015)

148

149 An important difference between conventional domes and superadobe or earthbag domes is the
150 angle formed between the centreline of the structure and the joint surface, as depicted in Fig. 2b.
151 In the case of conventional domes, joints are usually perpendicular to the centreline, which
152 tends to increase stresses normal to this surface. Consequently, shear stresses are reduced and
153 the shear strength of the joint is increased. On the contrary, in the case of superadobe domes, the
154 centreline is inclined regarding the joint surface, leading to a reduction of the normal stresses
155 and an increase of the tangential stresses. This intensifies the risk of failure of the joint, whose
156 behaviour should be carefully verified.
157 The method proposed here applies to the design of earthbag and superadobe walls and domes,
158 taking into account the special behaviour of the joints as well as the discontinuity introduced by
159 openings. As in other methodologies for the design of dome-like structures, some
160 simplifications are assumed. Specific calculations with more accurate tools should be performed
161 in complex structures or in structures subjected to unusual boundary conditions.

162

163 **3. SUPERADOBE WALLS**

164

165 This section focuses on the design of superadobe walls. First, the basis for the structural
166 verification is set. Then, a parametric study is conducted considering different geometries and
167 material properties.

168

169 **3.1 Stresses and structural verification**

170

171 The walls usually receive forces at the top - observed especially in case it gives support to a
172 dome or to other covering element. The external resultant force (F_d) may be applied as indicate
173 in Fig. 3a.

174

175

Fig. 3 - Forces N_d, T_d and M_d acting on the wall (a), combined bending and axial compression in a row (b), stresses in a bag under vertical loading (c)

178

179   F_d is equivalent to a normal component (N_d), an horizontal component (T_d) and a bending force
180   (M_d) due to the eccentricity. The normal force applied in each interface increases in lower bags
181   as the weight of the upper part of the wall increases. The horizontal forces and the bending
182   moment vary due to the effect of lateral loading, such as wind forces (W_d). Fig. 3b shows the
183   combined application of bending and axial forces in a row, which produce a non-uniform stress
184   distribution in the interface. Notice that the application of the normal stresses should also induce
185   tangential stresses because of to the lateral confinement created by the bag, as shown in Fig. 3c.
186   To simplify the description of the formulations, all variables are described in the list of symbols.
187   In general, the letter i is appended as a subscript to the variables in order to make reference to
188   the calculation at a certain earthbag row. In case the letter i do not appear as a subscript, the
189   variable makes reference to the global analysis of the wall, considering the boundary conditions.
190   The resistant and failure mechanisms of the wall are determined by considering the design
191   values of the forces (N_d, T_d, M_d, W_d) and of the stresses. In order to guarantee the structural
192   safety, the design value of the strength (S_d) should be bigger than or equal to the stresses
193   generated by the actions (A_d). In other words, the safety factor (SF) shown in Eq.1 should be
194   bigger than 1.

195

$$SF = S_d / A_d \qquad \text{(Eq.1)}$$

196

197   Vertical stresses generate a horizontal component to the bag due to the lateral earth pressure of
198   the soil when subjected to normal loads. The bag is responsible for resisting these stresses
199   (Tantono 2007, Pelly 2010, Vadgama 2010), which may be calculated as indicated in Eq.2 and
200   Eq. 3 for the row i.

201

$$\sigma_{d,v,i} = \frac{N_{d,i}}{bL} + \frac{6(M_{d,i} + T_{d,i}z_i)}{b^2 L} \qquad \text{(Eq.2)}$$

$$\frac{\sigma_{d,v,i}}{\sigma_{d,h,i}} = K_p \qquad \text{(Eq.3)}$$

202

203 Taking the expression above, the global stability of the wall and the local stability of each bag

204 or joint have to be verified. Table 2 shows the equations that were deducted based on the

205 principles of material and structural mechanics for the verification of the possible failure

206 mechanisms that might occur considering the specificities of superadobe walls.

207

208 *Table 2 - Equations for structural verifications in walls*

Mechanism	Verification	
Collapse *(Fig. 4a)*	$f_{ground} \geq \sigma_{d,v,1}$	(Eq.4)
Buckling *(Fig. 4b)*	$\pi^2 b^3 L E_{adobe}/(48H^2) \geq N_{d,max}$	(Eq.5)
Roll-over *(Fig. 4c)*	$N_{d,i} b/2 \geq M_{d,i} + T_{d,i}h$	(Eq.6)
Slipping *(Fig. 4d)*	$c_{bw}bL + N_{k,i}\mu \geq T_{d,i}$	(Eq.7)
Tear of the bag *(Fig. 4e)*	$T_{tear} \geq T_{d,i} - N_{d,i}\mu$	(Eq.8)
Failure of the adobe *(Fig. 4f)*	$f_{adobe} \geq \sigma_{d,v,i}$	(Eq.9)
Failure of the bag *(Fig. 4g)*	$2K_p T_{bag}/h \geq \sigma_{d,v,i}$	(Eq.10)

209

210 As indicated in Table 2, several conditions have to be simultaneously satisfied in order to avoid

211 the global or the local collapse of the structure.

212 • Collapse of foundation: The ground strength (f_{ground}) must be larger than the vertical
213   stresses at the bottom row of the pile (see Eq.4).

214 • Buckling of the structure: The maximum axial force should be smaller than the critical
215   load obtained according with Euler's formulation for a simply supported element (see
216   Eq.5).

217 • Roll-over: The destabilizing bending forces should be smaller than the stabilizing ones
218   (see Eq.6).

219 • Slipping of the bags: The tangential force should be smaller than the resistance of the
220   interface, which was assessed using a Coulomb Friction model using the cohesion and
221   the static friction of the interface (see Eq.7).

222 • Tear of the bag: The tear strength should be larger than the tangential force minus the
223   static friction (see Eq.8).

224 • Failure of the adobe and the bag: The vertical stresses must be smaller than the adobe
225   yield stress and the bag yield stress multiplied by the coefficient of lateral earth pressure
226   (see Eq. 9 and 10, respectively).

227 The graphic representation of the each failure mechanism is depicted in Fig.4. Notice that the

228 strength of the materials corresponds to the age of the material at the moment of conducting the

229 verifications. This is especially relevant in case a binder is used in combination with the soil.

230 Usually, the most critical situation in terms of resistant capacity takes place just after the

231 construction, before the bags have degraded and an improved connection develops between the
232 materials from different rows.
233

235 *Fig. 4 - Possible failure mechanisms: global collapse (a), buckling (b), roll-over (c), local slipping (d),*
236 *tear of the bag (e), adobe failure (f) and bag failure (g)*
237

3.2 Parametric study

239

240 A parametric study was conducted to analyze the influence of geometric and design variables in
241 the structural response. In practice, the boundary conditions, the geometries and the material
242 properties may vary considerably depending on each location. The selection of parameters and
243 their ranges was based on values reported in other studies from the literature and previous
244 experiences by the authors. The main idea was to cover the typical cases of superadobe
245 structures found in practice. Table 3 shows the parameters considered for the study and their
246 values. In particular, the values regarding the mechanical properties were chosen from studies in
247 the literature (Daigle 2008, Pelly 2010, Vadgama 2010, Croft 2011) and the range of design
248 forces is roughly estimated assuming the weight of the roofing, the live load as well as the wind
249 and snow loads. The dimensions of the walls were defined based on the common values
250 appearing in superadobe projects and buildings (Khalili 1986, Hunter 2004, Geiger 2011).
251

252 *Table 3 - Geometric and material properties for the parametric study of the walls*

N_d (kN)	T_d (kN)	M_d (kNm)	B (m)	H (m)	D (kN/m³)	K (-)	E_{adobe} (kN/m²)	f_{adobe} (kN/m²)	f_{ground} (kN/m²)	T_{bag} (kN/m)	T_{tear} (kN)	C_{bw} (kN/m²)	μ_{bags} (-)
1 to 15	0 to 2	$0.06N_d$	0.25 to 0.45	0.50 to 2.50	19	2.40	10000	2000	200	10	0.14	5.50	0.67

253

254

255 *3.2.1 Parameters influence in the structural safety*

256

257 The analysis in this section focuses on the influence of the parameters studied in the critical
258 verification of all equations presented in Table 1. Three load cases are considered for the
259 variation of the design forces: the axial force varies and the shear force is zero; an axial force of

260   10 kN and only the shear force varies; both parameters vary but the ratio N_d/T_d remains constant

261   in all cases. The safety factor was calculated for each failure mode in accordance with Eq.1.

262   The smallest *SF* obtained for different width of the bag (*B*) and a height of 2.5 m are presented

263   in Fig.5a, 5b and 5c. In this figure, the vertical axis corresponds to the structural *SF* and the

264   horizontal axis depicts the values of the parameter studied. Notice that a value equal or lower

265   than 1 in the vertical axis indicates that at least one verification is not satisfied. This limit is

266   depicted as a red continuous line in all graphs. The predominant failure mode is also indicated

267   by the type of marker used in each curve.

268   Fig.5a, 5b and 5c reveal that *B* is a key parameter regarding the structural safety. To achieve *SF*

269   bigger than 1, *B* bigger than 0.35 is needed in practically all scenarios simulated in this

270   parametric study. As expected, the influence of *B* is highly sensible to the normal action at the

271   top of the wall (N_d). The variation in the *SF* as a result of modifications of the tangential action

272   (T_d) is considerably smaller for the typical range found in practice. This is reasonable since the

273   most likely failure modes are due to buckling and to roll-over of the wall, both of which depend

274   mainly of the area of the cross section of the wall and of the normal actions.

275   Interestingly, as the normal forces decreases and the width increases, the critical condition tends

276   to be related with other boundary conditions and the predominant failure mode changes. As

277   observed in Fig. 5a and 5c, for the cases with N_d of 1 and B bigger than 0.3 m, the smallest *SF*

278   occurs for the collapse verification. The latter, is closely related with the ground mechanical

279   properties. Other parameters such as the compressive strength of the adobe (f_{adobe}), the tensile

280   strength of the bag (T_{bag}), the contribution of the barbed wire (C_{bw}) or the friction coefficient

281   between bags do not have any influence in this case of study since they are not related with

282   failure due to global or local roll-over nor buckling.

283   Another important variable during the design process is the height of the structure (*H*). The

284   influence of this parameter on the structural safety is presented in Fig. 5d, 5e and 5f for a

285   constant *B* of 0.45 m. Again, different conditions in terms of N_d and T_d are considered. In

286   general, the increase of *H* leads to a reduction of the *SF*. The exception is observed when the

287   predominant failure is due to roll-over and low normal forces are applied. In this case, the

288   increase of height produces an increase of the compressions at the base of the column. Such

289   compressions stabilize the wall and reduce the risk of failure due to roll-over, thus increasing

290   the *SF*. As a higher N_d is applied, the failure becomes governed by the collapse or the buckling,

291   which are negatively influenced by the increase of *H*. Consequently, a decrease of the *SF* is
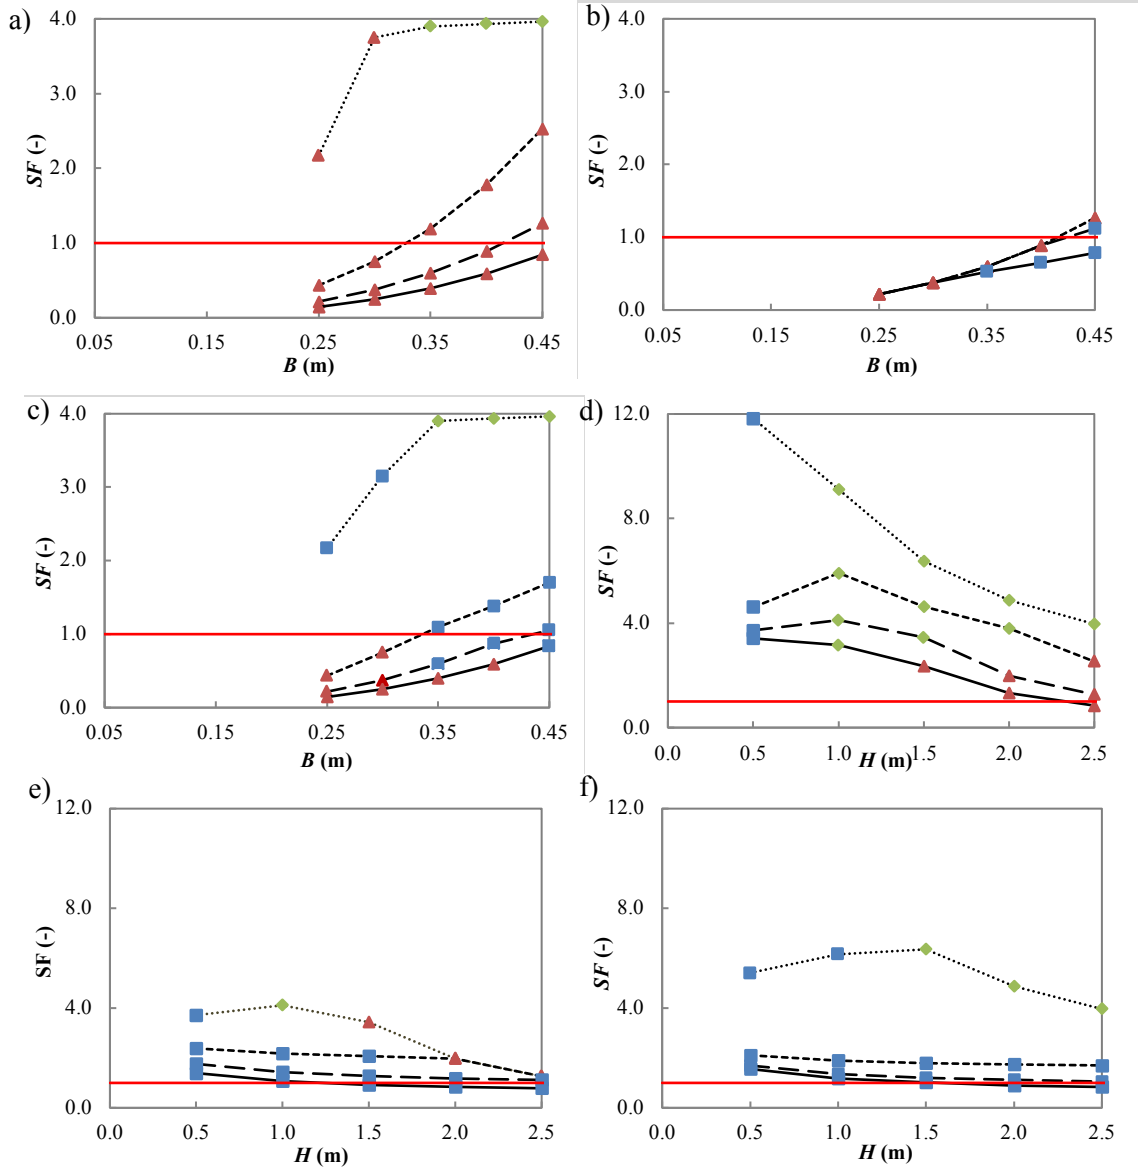

292   observed with the increase in *H*.

293

294

295

296

Fig. 5 - Influence of the width of the bag (a, b and c) and height of the wall (c, d and e) on the SF

297

298

299   Notice that the *SF* is bigger than 1 for most of the simulations performed. The only exceptions

300   occur for walls with *H* bigger than 2 m and is subjected to high N_d values. In such cases, the *SF*

301   against buckling and roll-over becomes smaller than 1. In other words, instability problems

302   become more evident for heights of more than 2 m.

303

304   *3.2.2 Interaction axial force and shear force diagram*

305

306   In order to gain deeper insight into the structural performance of earthbag walls, an axial force

307   and shear force interaction diagram is developed by means of the equations from Table 1,

308   considering a height of the wall (*H*) equal to 2.50 m and the width of the bag (*B*) equal to 0.45

309   m. The normal force that generates *SF* equal to 1 is calculated for each value of shear force

10

acting at the top of the wall. This calculation is repeated for all failure mechanisms. The resulting diagram is depicted in Fig. 6. An arrow is placed over the curves to indicate whether the safe region regarding each failure mechanism is located above or below the corresponding line. The overall safe region where all verifications are simultaneous fulfilled and the typical load found in practice are also depicted in the figure.

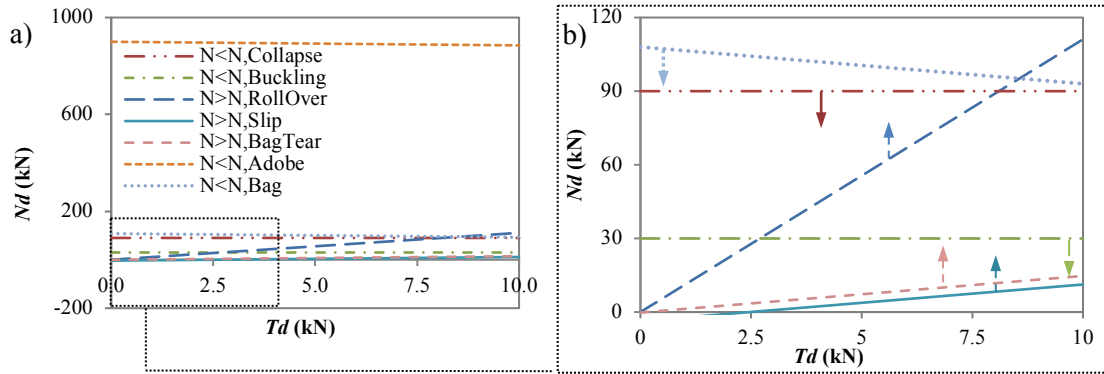

Fig. 6 - Axial and shear forces interaction diagram (a) and zoom of safe region (b)

The load required for producing collapse, bag failure and adobe failure are far above the typical load found in practice. The unsafe region regarding the bag tear and the bag slip covers only a small portion of the typical load area, thus indicating that these modes are not likely to lead to failure. The overall safe region corresponds to the limits established by the expressions regarding buckling and global roll-over. The buckling failure curve is a constant straight line that defines the maximum axial force 30 kN, whereas the global roll-over curve exhibits a constant slope that establishes the relationship between the axial and shear forces. Notice that the typical load area is not completely overlapping with the overall safe region, which suggests that the current design might be unsafe. This is mostly due to the high slope of roll-over failure curve. It is important to remark that an isolated wall was considered in this simulation. In many practical situations, the presence of lateral walls increases the stiffness of the structure, thus reducing the slope of the roll-over failure curve.

4. SUPERADOBE DOMES

This section focuses on the structural design of superadobe and earthbag domes. The analysis of typical geometries is presented along with the method for the calculation of the stresses in the bags and in the joints. A structural verification of the bearing capacity is also proposed. The results obtained are compared with those derived from the application of alternative methods from the literature.

4.1 Geometrical considerations

342

The superadobe dome presents several particularities when compared with conventional continuous dome structures. The most important of them is related with the material used and the fact that the interaction between biodegradable bags has to be taken into account. Table 4 presents the equations that define geometrically typical shapes of superadobe dome.

347

Table 4 - Equation for the possible arch curvature in height

	Variable arch	Pointed arch	Parabolic arch	Elliptic arch
Equation	$x = \sqrt{\left(\frac{\emptyset}{2}+d\right)^2 - z^2} - d$ (Eq.11)	$x = \sqrt{(\emptyset+b)^2 - z^2} - \left(\frac{\emptyset}{2}+b\right)$ (Eq.12)	$x = \sqrt{\frac{\emptyset^2}{4}\left(1-\frac{z}{H}\right)}$ (Eq.13)	$x = \frac{\emptyset}{2H}\sqrt{H^2 - z^2}$ (Eq.14)
Cross section				

349

The most common shape is the "pointed arch" due to its simple construction procedure and its bearing capacity (the geometry provides a significant percentage of rows subjected to compression along the perimeter). While the "pointed arch" and "equilateral arch" only require two ropes to define their geometry, the parabolic and the elliptic ones require a prior set of measurements with regards to the centre of the dome. This might complicate the constructive procedure and should be considered when assessing the optimal shape of the dome.

Among the methods available in the literature to evaluate the stresses of dome-like structure are the membrane theory (MT) and the graphical analysis (GA). The former only applies to pointed arches, whereas the latter applies to any shape. Both of them assume a continuous transmission of stresses along the height, not contemplating the discontinuities introduced by the interfaces between bags. Even though the current design rules (CR) proposed by Khalili (1986) to the design of superadobe domes take that into account such discontinuities, it only applies to pointed arches. The method proposed in the next sections is valid for all superadobe domes, regardless of their shape.

364

4.2 Method to estimate the design forces and stresses

366

In the design of earthbag and superadobe structures it is essential to consider that the behaviour of the adobe and the bag varies over time. This affects significantly the structure and the way

369   the calculations must be made. For early ages, the dome may be assumed as the succession of

370   rows piled one on top of the other, whereas in the long term the dome will behave as a shell

371   stone structure. For this reason, the conventional dome cannot be considered as a reference in

372   the design at early ages.

373   All these aspects were taken into account for the development of the design method. The

374   method is based on the verification that the design forces and stresses do not compromise the

375   stability or lead to mechanical failure. A horizontal force (F_h) needed to centre inside the kern

376   section limits of each row the resultant of the part of the dome located above it is calculated. It

377   is assumed that this force is withstood as shear forces between rows (T_d) or hoop forces along

378   the perimeter of the rows (σ_θ), as shown in Fig. 7. In order to facilitate the comprehension of the

379   method, it was divided in the following seven steps. The equations applied in each step are

380   summarized in Table 5.

381

382   1.   Calculate the inner (Eq.15), central (Eq.16) and outer radius (Eq.17) of each row defined

383   by the corresponding shape of the dome (Eq.11-14).

384   2.   Classify rows as continuous or discontinuous depending on the presence of open spaces.

385   When the row is continuous define whether bag is capable of bearing hoop stresses or not.

386   3.   Calculate the inner (Eq.18) and outer contact effective limits (Eq.19), the limits

387   corresponding to the kern section (Eq.20-Eq.21) (see Fig.7a) and the contact area between

388   rows (Eq.22).

389   4.   Calculate the weight of each row (Eq.23), the accumulated weight (Eq.24) and the position

390   of the centre of gravity of the accumulated weight (Eq.25-26) (see Fig.7b). Repeat this

391   process for any other type of load acting above the row.

392   5.   Calculate the maximum (Eq.27) and minimum (Eq.28) horizontal forces needed to displace

393   the resultant force towards the kernel section limits (see Fig.7b) of each row.

394   6.   Calculate the axial force (Eq.29), the bending moments (Eq.30-31) and the shear force

395   (Eq.32-33) for each row (see Fig.7c).

396   7.   Calculate the axial stress (Eq.34) through the ratio between the vertical axial force and the

397   effective contact area between consecutive rows. Then, calculate the stress at the most

398   exterior point of the contact (Eq.35) due to the bending moment induced by the weight (see

399   Fig 7d). Finally, calculate the horizontal tensile stress (Eq.36, see Fig.7e). For rows capable

400   of generating hoop forces, calculate the hoop stress in case of compression (Eq.37) or
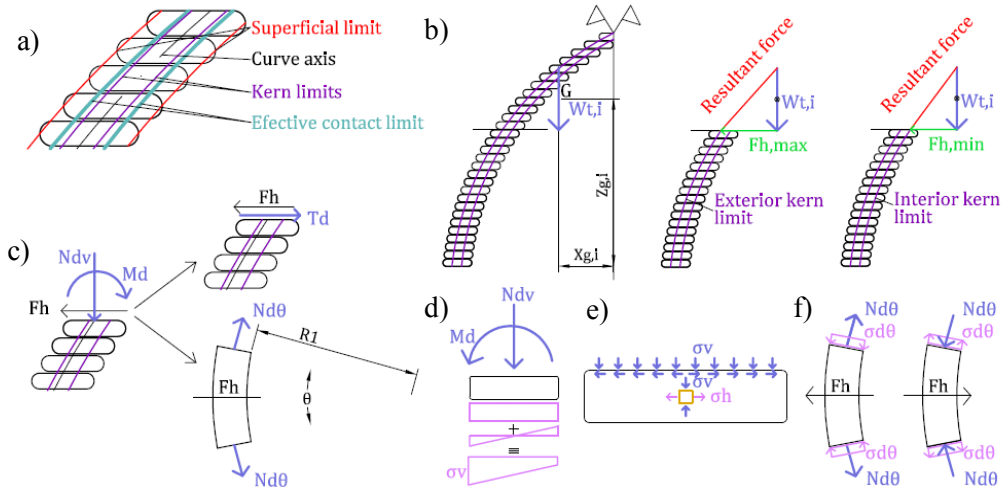

401   traction (Eq.38).

3	$R_{ef,int,i} = RI_i$	(Eq.18)		$M_{d,min,i} = N_{d,v,i}(R_{kl,int,i} - RC_i)$	(Eq.30)
	$R_{ef,ext,i} = RE_{i-1}$	(Eq.19)		$M_{d,max,i} = N_{d,v,i}(R_{kl,ext,i} - RC_i)$	(Eq.31)
	$R_{kl,int,i} = RC_i - b_i/6$	(Eq.20)		$T_{d,i} = Fh_{max,i} \gamma_{G1}$	(Eq.32)
	$R_{kl,ext,i} = RC_i + b_i/6$	(Eq.21)		$T_{k,i} = Fh_{min,i} \gamma_{G2}$	(Eq.33)
	$A_{z,ef,i} = 2\pi RC_i(R_{ef,ext,i} - R_{ef,int,i})$	(Eq.22)	7	$\sigma_{v,i} = -\dfrac{N_{d,v,i}}{A_{z,ef,i}}$	(Eq.34)
4	$W_i = \gamma_N 2\pi RC_i b_i h$	(Eq.23)		$\sigma_{ext,max,i} = \sigma_{v,i} - \dfrac{3M_{d,max,i}}{\pi RC_i b_i^2}$	(Eq.35)
	$Wt_i = \displaystyle\sum_{j=imax}^{i+1} W_j$	(Eq.24)		$\sigma_{h,i} = \dfrac{\sigma_{v,i}}{K_p}$	(Eq.36)
	$Xg_i = \dfrac{\sum_{j=imax}^{i+1} W_j RC_j}{\sum_{j=imax}^{i+1} W_j}$	(Eq.25)		$\sigma_{d,\theta,c,i} = \dfrac{(Fh_{min,i} - Fh_{max,i-1})\gamma_{G1}}{2\pi b_i}$	(Eq.37)
	$Zg_i = \dfrac{\sum_{j=imax}^{i+1} W_j Z_j}{\sum_{j=imax}^{i+1} W_j}$	(Eq.26)		$\sigma_{d,\theta,t,i} = \dfrac{(Fh_{max,i} - Fh_{min,i-1})\gamma_{G1}}{2\pi b_i}$	(Eq.38)

409

410 Notice that in the method proposed here, the forces needed to assure that the resultant coincide

411 with the inner and outer kern limits of the cross section are considered. This provides an

412 envelope of forces that mark a limit condition. In safe structures, the real stress will be smaller

413 than the defined with this method. Conversely, if the estimated stresses fall outside these limits,

414 failure or collapse might occur.

4.3 Structural verification

The verifications required to confirm the capacity of the superadobe domes to resist the actions applied depend on the behaviour expected from each row. In case openings are presents, the row is considered discontinuous, not being able to bear hoop stresses and falling in the category Ds. In case no opening is present, the row is considered continuous and the designer may decide whether the bags and the adobe are capable of resisting hoop stresses. If the material is capable of bearing both compressive and tensile hoop stresses (the adobe and the bag contribute to the resistant capacity), it falls in the category $C_{A\&B}$. If the material is capable of bearing only compressive hoop stresses (the adobe contributes to the resistant capacity but the bag does not), it falls in the category C_A.

Table 6 shows the expressions for the verification of the failure and resistant mechanisms corresponding to superadobe domes, which are depicted in Fig. 8. The verifications depend on the row classification (D_s, $C_{A\&B}$ or C_A). Mandatory and recommended verifications are indicated by the letters M and R, respectively. Notice that the failure mechanisms are analogous the ones described for the superadobe walls in section 3.1.

4.4. Comparison with finite element numerical simulation

4.4.1 Description of the FEM

In order to confirm that the method proposed shows reasonable structural response, numerical validations with finite element simulations were performed. The finite element program "TNO Diana 9.3" was used for this purpose. An axisymmetric model was selected due to the geometry of the dome. Bags were represented by triangular elements with an integration point at each side and maximum dimension of 10 mm. Fig. 9a shows the mesh used in this study.

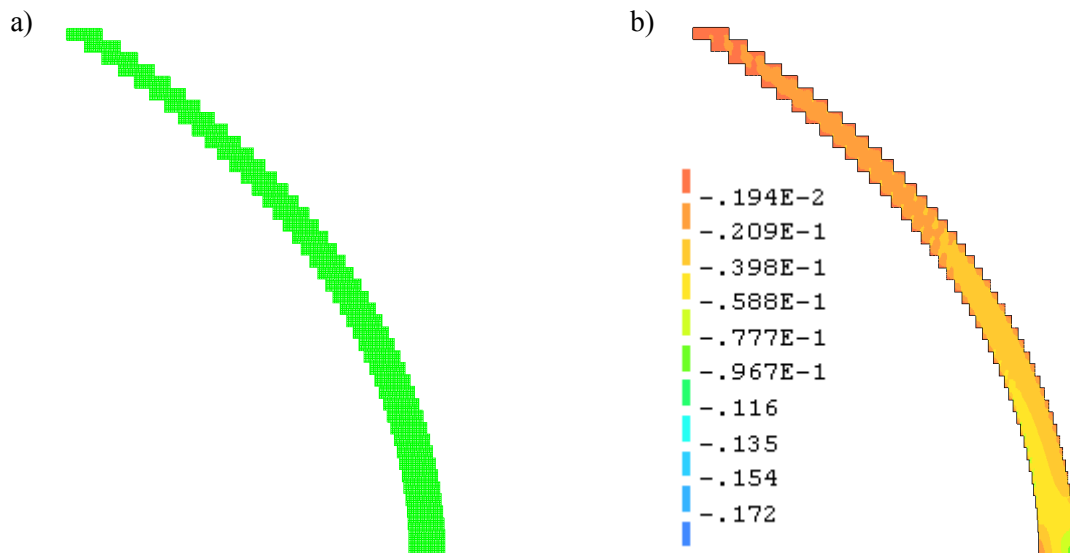

Fig. 9 – Mesh used in the study (a) typical stress distribution in MPa in the vertical direction (b)

455   The constitutive model used for the earthbag shows an elasto-plastic behaviour in compression.

456   It follows the Hook's law with strains linearly proportional to stress until the yield stress of the

457   adobe is reached. Once this occurs, the strain increases without any increment of the stress. A

458   brittle failure in tension with cut-off strength of 0 MPa is assumed to simulate the behaviour of

459   the adobe at early ages. Structural interface elements were placed in the joint between earthbags

460   to simulate their interaction. A Coulomb Friction model was used to capture the possible sliding

461   in the interface. This model requires the input of a cohesion value and a friction coefficient.

462   Table 7 shows the elastic modulus (E_{adobe}), Poisson ratio (v) and the density (D) of the adobe

463   used in all analyses. The same table also presents the cohesion (C_{bw}) and the friction coefficient

464   (μ_{bags}) of the interfaces.

465

466   *Table 7 - Geometry and material properties for the comparison with the FEM*

B (m)	b (m)	h (m)	D (kN/m³)	K_p (-)	E_{adobe} (kN/m²)	v (-)	C_{bw} (kN/m²)	μ_{bags} (-)

467

468

469   The displacement of the lowest row of earthbags was fully restrained. The load consisted of the

470   self-weight of the elements applied in the direction of the height of the dome. The tenth part of

471   the self-weight was applied in 10 successive steps to evaluate the arising of material

472   nonlinearities. The solution to each load step was obtained through an iterative procedure based

473   on the Newton-Rapson approach. Fig. 9b shows a typical stress distribution obtained after the

474   load is fully applied.

475

477   *Fig. 10 - Arches simulated: constant the radius and variable height (a), constant height and variable the*

478   *radius (b)*

479

480   A parametric study was conducted by varying the height and the radius of an ogival arch as

481   shown in Fig.10a and Fig.10b. In the analysis of the influence of the height, values ranging from

482   2.6 m to 3.2 m were used for an inner radius of 2.0 m. For the analysis of the influence of the

483   inner radius, values ranging between 1.7 m and 2.3 were used, considering a height of 2.9 m.

484   Other geometric parameters assumed in the simulations are summarized in Table 6. In total 10

485   models were analysed. No partial safety factor was applied to the loads or to the material

486   properties. After the analysis, the resultant force was calculated at each height through a

487   weighted sum of the forces acting at all nodes at this height.

488

489   *4.4.2 Results of the FEM*

490

491   Fig. 11 shows the results obtained with the finite elements models (FEM) and in the design

492   method proposed here (MP). Fig. 11a, 11b and 11c represent the variation of vertical (σ_v), shear

493   (τ) and hoop (σ_θ) stresses for models with different height (h1 to h5). Fig. 11d, 11e and 11f show

494   analogous results for models with different radius (r1 to r5).

495

Fig. 11 - Comparison of vertical (σ_v), shear (τ) and hoop stress (σ_θ) computed by MP and FEM for different curvatures: varying the height (a, b, c) and varying the radius curves (d, e, f)

503   The vertical stresses increase almost linearly with the height as a consequence of the increase of

504   the number of rows supported. The vertical stresses computed with the model proposed here and

505   the finite element simulation are almost the same for all curves. Small differences may be

506 attributed to the procedure of calculation of the stresses in the latter since an averaging
507 procedure has to be applied.

508 The shear stress obtained at the top of the dome is approximately 0 MPa since the key element
509 is at a stable position. These stresses increase rapidly as the height reduces. Tangential forces
510 are needed to guarantee compatibility and to divert the resultant force of the upper rows due to
511 the change in the radial position of the cross section centre of gravity at each height. For the
512 same reason, at lower height, the smaller change in radial position of successive rows implies
513 smaller values of shear stress. Even though the shape of the curves is similar, the stresses
514 calculated with the methodology proposed here is considerably higher than the calculated
515 through the finite element analysis. This result was expected since the proposed method shows a
516 limit situation that could lead to collapse or local failure.

517 The hoop stresses computed in the finite element simulation changes direction along the height
518 of the dome. This is a consequence of the compatibility of displacements experienced by the
519 dome. The simplified method proposed does not take into account these deformations, which
520 otherwise would compromise the simplicity of the calculations. Consequently, it is not able to
521 capture the change in the direction of the hoop stresses. Despite that, the fact that the calculation
522 is performed for the outer and inner limits of the kern of the cross section for compression and
523 tensile forces provides maximum and minimum values. Notice that all curves obtained with the
524 finite element simulations remain within the limits defined by the curves of the simplified
525 method. This confirms that the simplified method will always remain on the safe side.

526

527 **4.5. Comparison with other simplified approaches from the literature**

528

529 To understand the repercussion of the new design method proposed, a comparison with other
530 simplified approaches from the literature is made. In total, three approaches were selected: the
531 graphical analysis (GA) (Wolfe 1921), the membrane theory (MT) (Billington 1982) and the
532 current design rules (CR) (Khalili 1986). All analyses were conducted considering the
533 geometric and material properties from Table 7 and a pointed arch shape. Fig.12a compares the
534 minimum bag width required to build domes with diameter (ϕ) ranging from 3.0 m to 6.0 m.

535 Fig. 12a indicates that the current design rules (CR) and the model proposed here (MP) give
536 similar design for diameters bigger than 4.0 m. For diameters of less than 4.0 m, MP yields
537 smaller thickness than the CR. This indicates that the CR might lead to an overestimated design,
538 which may be attributed to some simplifications assumed in this method. Notice that for a 5.0 m
539 dome, the optimized bag size is 0.45, 0.65, 0.65 and 0.85 for MT, CR, MP and GA,
540 respectively. This indicates that GA overestimates the minimum bag width by 70% in
541 comparison with CR and MP. Such outcome may be attributed to the fact that the resultant from

542   the GA tends to fall outside the kern of the earthbags. Consequently, it is necessary to increase

543   the width to assure that forces falls within these limits.

544

545

546   *Fig. 12 - Comparison of dome design following MP, CR, MT and GA; range of stabilizing angles of CM*

547   *to obtain the same moment than MP (b and c)*

548

549   On the contrary, the MT underestimates the results from CR and MP by 10%. The reason for

550   that is the limited capacity of the MT to capture the failure mode observed in the domes, which

551   is due to local roll-over. This type of failure is only observed in the domes analyzed with the

552   MT in case very small width is used. In other words, it only occurs for domes with smaller

553   width.

554   A new method for the analysis of superadobe domes is the modified corbelling theory (CM)

555   (Rovero and Tonietti 2012, Rovero and Tonietti 2014). The latter introduces a stabilizing

556   parameter in order to add the contribution of the hoop curvature on the over-roll equilibrium.

557   This parameter is called α and is the influence angle that reduces the destabilizing moment and

558   increases the stabilizing one. The main inconvenient of the CM is that this parameter depends

559   on the characteristics of each dome, requiring experimental studies. It is important to remark

560   that a direct comparison with the corbelling theory (CM) is not possible since it does not

561   provide the design width of the dome. Despite that, a comparison is made in terms of the angle

562   α that has to be used in the CM to obtain the maximum and minimum bending moment

563   equilibrium found in the model proposed here. The angle obtained is compared with the range

564   typically found by Rovero and Tonietti (2014).

565   Fig. 12b and 12c shows the results obtained for the arch shapes of Fig. 10. Although lower

566   values are found at the upper part of the dome, the results indicates that the range of angles must

567   be between 60º and 85º on bottom rows. This range of α is in agreement with that estimated in

568   the studies with the CM based on experimental result from other authors, who found values of

569   72.5º and 75.7º for real domes (Rovero and Tonietti 2014).

570

571

573 **4.6. Parametric study**

574

575 Table 8 shows the range of variables and the fixed values of properties used in the parametric

576 study of the domes using the method proposed. Again, the selection of parameters and their

577 ranges intend to cover typical values found in practice, being based in studies from the literature

578 and on the experience by the authors. The arch is simulated in this case by changing the

579 parameter d' that governs the curvature according with Eq. 12. Variables are analysed one by

580 one, considering all other parameters with fixed values. In this sense, B, C_{bw}, μ_{bags} and d' are

581 assumed equal to 0.5 m, 6.0 kN/m^2, 0.6 and 1.0 m, respectively. The estimation of the safety

582 factor was performed as described in section 2.2 considering domes with discontinuous

583 behaviour (D_s) and domes with a continuous behaviour that are capable of resisting tensile and

584 compressive hoop stresses ($C_{A\&B}$). The diameters simulated ranged from 3.0 to 6.0 m.

585

586 *Table 8 - Geometric and material properties for the parametric study of the domes*

B (m)	d' (m)	φ (m)	D (kN/m³)	K_p (-)	E_{adobe} (kN/m²)	f_{adobe} (kN/m²)	f_{adobe_t} (kN/m²)	f_{ground} (kN/m²)	T_{bag} (kN/m)	T_{tear} (kN)	C_{bw} (kN/m²)	μ_{bags} (-)
0.3 to 0.6	0 to 1.5	3 to 6	19	2.40	10000	2000	20	200	10	0.14	0 to 6	0 to 0.6

587

588 Fig. 13a shows the influence of the width of the bag on the *SF*. The increase of width leads to a

589 consequent increase of the *SF* in the domes $C_{A\&B}$. This is reasonable given that the failure in this

590 case is governed by the roll-over to the outside in the rows close to the bottom of the dome. The

591 increase of the width leads to bigger contact areas, which contributes to the stability against this

592 type of failure and increases the *SF*. On the contrary, the predominant failure mechanism

593 observed in the discontinuous domes (D_s) is due to slipping between bags. In this case, the

594 higher self-weigh load induced by the bigger width leads to bigger tangential loads that

595 contribute to the slipping of the bags located at the zones close to the top of the dome, which are

596 subjected to reduced normal forces. Consequently, smaller *SF* are obtained as the width

597 increases.

598 The influence of the parameters C_{bw} and μ that determine the behaviour of the interface between

599 bags are depicted in Fig.13b and 13c. Notice that both parameters have no influence in safety

600 factor of the continuous domes since the main failure mechanism is due to roll-over and,

601 therefore, do not depend on the interface properties. On the contrary, the discontinuous domes

602 show a significant increase of the *SF* as C_{bw} and μ increase. This is reasonable since the failure

603 in this case is governing by the slipping of the bags, thus depending on the properties of the

604 interface.

605 Fig. 13d shows the influence of the curvature parameter *d'* on the *SF*. In general, the selection of

606 smother curvatures (bigger *d'*) leads to an increase on the *SF*. This becomes more evident as the

607 diameter of the domes increases. This outcome is reasonable since smaller tangential forces are

608 generated with smother curvatures, reducing the risk of global and local instabilities.

609

618

619

620 *Fig. 13 - Influence of the width of the bag (a), the cohesion of the interface (b), the friction coefficient*

621 *between bags (c) and the curvature parameter (d) on the safety factor and the optimal design of the*

622 *curvature parameter (e)*

623

624 Based on these results, an optimization analysis was performed to identify the minimum

625 curvature parameter (*d'*) that yields a *SF* equal to 1 for each combination of the width of the bag

626 and the diameter of the dome, thus minimizing the consumption of material and the construction

627 time. The curves obtained in this study are presented in the interaction diagram of Fig. 13e. The

628 results reveal that an increase in the diameter requires an increase in the parameter *d'*. In fact,

629 smoother curvatures are needed to cover bigger spans without generating critical tangential

630 stresses or the roll-over failure. It is also evident that the parameter *d'* tends to decrease with the

631 width of the bags for all diameters. Nevertheless, discontinuous domes or domes with smaller

632 diameter show a width above which the *d'* required increases. In other words, an optimum width

633 exists in these cases and could be determined through the use of the alternative method

634 proposed here.

635

22

6. CONCLUSIONS

The earthbag technique is an alternative to promote social housing and emergency shelters due its simplicity, fast construction and low cost. In spite of all this advantages, a lack of design methods that take into account the specificities of this type of structures might compromise its efficient and safe use. For that, several resistant mechanisms were identified and an alternative method for the design of walls and domes was proposed. This method takes into account the material properties and the capability of bearing tension on continuous hoops. The following conclusions may be derived from this study.

- The most probable failure mechanism in superadobe walls are the global roll-over and buckling. The increase of lateral stiffness is recommended to reduce the risk of these failure modes. The simulations performed suggest that the increase of stiffness will extend the resistance of the wall and change the most likely failure mode, which will be governed by failure or tear of the bag.

- The parametric study indicates that the wall width is the variable with greatest influence on structural safety, affecting in all the failure mechanisms considered. Conversely, the barbed wire contribution in straight walls is irrelevant because the slipping mechanism hardly ever will occur. In such situations, this material can be eliminated of the straight walls.

- The critical failure mode for the domes is the roll-over towards the outside that occurs close to the bottom and slipping close to the top. The width of the bags and the curvature of the dome are the most important parameters governing the structural response. It was found that for domes with big diameters and discontinuous domes, the increase of the width might lead to a reduction of the safety factor. In other words, an optimum width may be obtained.

- The application of the method proposed here allows the definition of optimization diagrams that relate the width of the bag, the curvature and diameter of the dome, as shown in Fig.13. These diagrams might serve as a fast reference to obtain the combination of parameters that minimizes the consumption of materials and the construction process.

- The method proposed has been verified with finite element simulations regarding normal vertical, shear and hoop stresses, for different dome sizes curvatures. The results obtained with the method proposed here is on the safe side for all cases analysed.

- Regarding to methodologies for the calculation of dome stresses, the membrane theory cannot capture the roll-over failure, which usually is the critical one; therefore the wall

672 size is underestimated. The use of graphical analysis yields an overestimated design.

673 For that reason, the use of the membrane theory and of the graphical analysis for the

674 design of domes should be avoided in favour of the method proposed here or of the one

675 proposed by Khalili (1986).

730

731 **Symbols**

732 A_d	Design value of the effects of actions
733 $A_{v,ef}$	Vertical effective contact area of a row
734 B	Bag width
735 b	Row width
736 C	Corbelled dome method
737 C_A	Continuous row
738 $C_{A\&B}$	Continuous row with bag bears hoop tractions
739 C_{bw}	Cohesion of the contact between joints with barbwire
740 CM	Corbelled dome method modified
741 CR	Current dome rules design
742 D	Adobe density
743 Ds	Discontinuous row
744 E_{adobe}	Adobe elastic modulus

745	f_{adobe}	Yield stress of the adobe
746	f_{ground}	Ground collapse load
747	Fh	Radial force
748	F_d	Design value of a force
749	FEM	Finite element method
750	GA	Graphical analysis
751	H	Structure total height
752	h	Row height
753	i	Row object to study
754	$imax$	Top row
755	I_x	Moment of inertia
756	K_p	Coefficient of lateral earth pressure
757	L	Wall length
758	M_d	Design bending moment
759	MP	Method proposed in this study
760	MT	Membrane theory
761	N_d	Design value of a normal force
762	N_k	Design value for a favourable normal force
763	q_{wind}	Wind load
764	RI	Inner radius
765	RC	Middle row radius
766	RE	Outer radius
767	RE_1	Outer radius of the first row
768	$R_{ef,int}$	Interior radius of the effective contact limit
769	$R_{ef,ext}$	Exterior radius of the effective contact limit
770	$R_{kl,int}$	Interior radius of the kern section limit
771	$R_{kl,ext}$	Exterior radius of the kern section limit
772	S_d	Design value of the strength effects
773	T_{bag}	Tensile strength of the bag
774	T_d	Design value of a shear force
775	T_{tear}	Tear strength of the bag per unit of length
776	W_{dome}	Total dome weight
777	W_i	Weight of the row section i
778	Wt_i	Total weight which received the row section i
779	x	Interior radial dome distance
780	Xg	Center of gravity in radial coordinates
781	Y_{max}	Maximum distance of neutral axis
782	Zg	Center of gravity in height coordinates
783	z_i	Height position
784	α	Stabilizing parameter for the corbelled modified theory
785	$\emptyset$	Interior dome diameter
786	γ_{adobe}	Adobe strength reductor coefficient
787	γ_{bag}	Bag strength reductor coefficient
788	γ_{G1}	Partial safety coefficient for a favorable permanent load
789	γ_{G2}	Partial safety coefficient for a unfavorable permanent load

790	γ_N	Specific weight
791	γ_{Q2}	Partial safety coefficient for a unfavorable variable load
792	γ_{wire}	Barbed wire strength reductor coefficient
793	$\sigma_{d,v,i}$	Design normal vertical stress of the row section i
794	$\sigma_{d,h,i}$	Design normal horizontal stress of the row section i
795	σ_v	Normal vertical stress
796	σ_h	Normal horizontal stress
797	σ_{ext}	Normal Stress on outer line
798	σ_θ	Hoop stress
799	$\sigma_{\theta,c}$	Hoop compression stress
800	$\sigma_{\theta,t}$	Hoop traction stress
801	τ	Shear stress
802	μ_{bags}	Friction coefficient of the contact between bags
803	v	Poisson coefficient α
