SUMMARY

The present work has arisen from a continuing need to improve the performance of round-steel lifting (hoist) and mining chains, and the hypothesis that this might be done by modification of the link geometry. The finite element (FE) method has been used to analyse the stresses in the chain links. The effects of link length and the bend radius in the crown were considered. The effect of maintaining link length constant and departing from the conventional straight sided (standard) geometry by changing the link shape from eight shape (pinched), through straight sided, to elliptical has been examined. Mining chains made from non-circular section rod have also been investigated. The finite element work has been supported by practical investigations using through-yield strain gauges.

The fatigue properties of the round-steel lifting chains have been investigated. Chains are often calibrated by application of manufacturing test force as one of the last manufacturing processes, to raise the load to which the chain will behave elastically in service. As a result, residual stresses are introduced, which improve the fatigue performance. The distribution of residual stresses has been examined by the finite element method and is compared with experimental results obtained by neutron diffraction, x-ray diffraction and strain gauge techniques. The best quantitative agreement between the FE predictions and experimental was obtained in the case of neutron diffraction.

In terms of the peak stresses for a given applied load, which result from combination of the residual stresses with the elastic stresses caused by loading, the conventional straight-sided link appears to be the optimum for a given rod diameter and pitch, although some benefit would result from a reduction in overall width.

CHAPTER 1

INTRODUCTION

1.1 INTRODUCTION

Chains manufactured from high-tensile steel are used in many applications, such as hoists, cranes, and in mining, where it is vital that their load-carrying capacity should be assured. The details of the manufacture of such chains may vary slightly but the following steps are generaly involved: cropping a length from bar-stock; forming the length to produce the next link on a continuous run of chain; butt or flash butt welding of the adjacent cropped ends of the link; and heat treatment of the welded chain by quenching and tempering. The temperatures used in heat-treatment (for the formation of γ Fe and the partial decomposition of martensite formed by quenching) depend on the steel used and the tensile strength required of the chain. Traditionally the final step is the application of a manufacturing test load, known as calibration in the trade, which is sufficient to deform the chain plastically and thus imparts the final dimensions to each link. It is now recognised that the residual stresses introduced by this process substantially affect the chain's mechanical properties and particularly its resistance to fracture under the effect of repeated tensile loads. However, there is no detailed knowledge of the magnitude or distribution of these residual stresses.

In this chapter, a brief background study is given regarding steel chains, their fatigue properties, the effect of residual stresses on fatigue properties, and the application of finite element analysis to chains. Objectives and the layout of the thesis are also given here.

1.2 ROUND LINK STEEL CHAINS

1.2.1 GENERAL

The chain is one of the most familiar as well as one of the most useful mechanical devices. Chains are mechanically strong, statistically reliable, and economical, and are used in many important components in hoists, slings, towing devices and conveyors.

Evidence of the manufacture of chains goes back to ancient times. The first chains were forged and fire-welded. At the end of the nineteenth century, finish-forming of the links using a die was introduced to improve accuracy. The turn of the twentieth century saw the first chain bending and chain welding machines (resistance welding method).

Increasing requirements with regard to quality, reliability and working life led to the development first of the heat-treated chains and finally to high-tensile chains. The development of corresponding welding methods ran in parallel. Apart from the previously mentioned resistance welding method, the so-called flash butt welding must also be mentioned because it permits welding not only of large nominal diameters but also highly alloyed steel.

1.2.2 TENSILE STRENGTH OF CHAINS

The tensile strength of chains is determined mainly by the material, the shape, and the surface conditions of use. Wear resistant materials with a high breaking strength combined with a high ductility, high notch impact strength and a high degree of surface

hardness are preferred for round steel chains. Chains must comply with the strain values specified in the appropriate standards; these can be obtained by stretching the chain. In BS3114 a specified minimum ratio of extension to length at a stated load is required in order to assume adequate energy absorption properties, Appendix A. Occasional overloads in operations should not lead to fracture, but merely to plastic changes in length. Wellinger [1] reported that the static strength of chains is approximately 60 - 70 % of the tensile strength of the material. The elongation decreases with increasing ratio (t:d) where t is inside length of chain and d, the diameter of the wire or rod from which the link is made.

1.2.3 MATERIAL

Depending on their application, chains are made of either plain carbon or high-tensile alloy steel. Manufacture of high tensile chains calls for a steel which can provide a tensile strength of 1200 to 1400 MPa after tempering, depending on quality grade, and in addition has adequate ductility (minimum elongation 14 %) and a high degree of notch impact strength as well as being weldable and having a high fatigue strength.

1.2.4 STRESS

It is essential to know operational stresses and their change, frequency and sequence with respect to time in order to evaluate safe working conditions and service life of a chain. The effect of chain shape on the tensile strength of the chain is illustrated by the stress charateristic of the short link chains shown in Fig. 1.1 [2,3]. The stresses in chain links with parallel side members (Fig.

1.1c) are lower than in those of a barrelled shape (Fig. 1.1a) and slightly higher than those in a link with a centre web (Fig. 1.1b). Wellinger [1] reported that for stressing below the elastic limit, for short link chains the region of highest tensile stress is the inside of the flank at the junction of the intrados with the straight sides (transition): for long link chains it is the outside of the crown. Maximum tensile stress was almost four times the nominal stress.

Hawkes et al [4] have reported that for short link chains at loads up to and just beyond elastic limit the position of the maximum stress occurs at the transition. Beyond the elastic limit, however, changes in link geometry cause the position of the maximum stress to move to the link crown as shown by use of the photoelastic-coating technique. On the other hand, theory predicts that the position of maximum stress in short link chains loaded elastically in tension is the crown [5]. This anomaly is due to the fact that the theoretical work assumed point loading between adjacent links and took no account of "bedding down" of the links.

The change in the pitch of a circular cross-section chain link has been investigated by employing the method of complementary work with plastic material properties [6]. The results of the work may be used in solving a number of practical problems connected with the determination of the change in pitch and load-bearing capacity of a different cross-sectional shapes. The results are particularly applicable to the standard link geometry and are not based on the detailed deformation of the chains.

1.3 BRITISH STANDARDS FOR ROUND LINK STEEL CHAINS

British Standards for lifting gear were first discussed some forty years ago. Various standards have since been drawn up which specify the dimensions of components, the material from which they must be made, the tests they must undergo before they can be given a certificate and all other information necessary to make them as safe as possible. A continual watch is kept by the relevant British Standards Institution committeeson improvements in design, material and manufacturing technique and on changes in requirements. When necessary, modifications to the standards are made.

From the early standards, a formula was developed at NPL which, given the link dimensions and design stress, determined the design load [7,8]. The formula has stood the test of the time and has, by an increase in the design stress, been the basis for the design of links made of the new, stronger, alloy steels. The formula is applicable to all chain links [9].

Anthony et al [7] proposed two empirical formulae for the diameter D_2 (Fig. 1.3) required for a link to have a particular working load limit W:

$$D_2 = .2 \, A \, B \, [\, 6.7 + A - B/L \,]$$

$$D_2 = B \, [\, .1 + A \, (1+A) - .12 \, L/B \,]$$

where L is the internal length of the link.
B is the breadth of the link.
$A = [\, W/fB \,]$
W being the working load limit of the link.
f being the maximum nominal extreme fibre stress in the link under the working load limit.

The two values predicted for D_2 seldom differ by more than almost 1.5 %, the larger of the two being selected in practice.

BS 4942 [10,11,12,13,14,15],'Short link chain for lifting purposes',

specifies the general conditions of acceptance for electrically welded
round steel short link chain for lifting purposes. It includes
non-calibrated (see Section 1.1) chain use in cranes, in chain slings
and for general lifting purposes and calibrated chain for use with
chain hoists and other lifting appliances: they will be referred as
lifting chain in what follows.

BS 6521 [16],'Proper use and maintenance of calibrated round steel
link lifting chain', specifies the principles for the use, inspection,
in-service testing and maintenance of calibrated round steel link
chains operating over chain wheels. The principal applications
include manual and power driven hoists.

'Hoist designers handbook' [17] and 'a guide to Safety practices for
chain sling' [18] may also be consulted in relation to the BS 6521.

BS 2969 [19],'High-tensile steel chains (round link) for chain
conveyors and coal plough', specifies the requirements for a range of
high grade special purpose calibrated, high-tensile electrically
welded, steel chains for use with machines and equipment in mining and
they will be referred as mining chain in what follows.

BS 6405 [20],'Non-calibrated short link steel chain (grade 30) for the
general engineering purposes: class 1 and 2' (mean stress at
specified minimum breaking load is 300 MPa). This standard deals with
non-calibrated short link steel chain of grade 30 for general engineering
purposes and provides for two qualities, class 1 quality chain for
arduous duties such as lashing or load binding and class 2 quality
chain for general duties.

1.4 FATIGUE

1.4.1 GENERAL

Fatigue is the progressive localised permanent structural change that occurs in a material subjected to repeated or fluctuating strains at stresses having a maximum value less than the tensile strength of the material. Fatigue may culminate in cracks or fracture after a sufficient number of fluctuations.

Fatigue fractures are caused by the simultaneous action of cyclic stress, tensile stress and plastic strain. If any one of these three is not present, fatigue cracking will not initiate and propagate. The cyclic stress starts the crack; the tensile stress produces crack growth (propagation). Although compressive stress will not cause fatigue, compression loads may do so, because of tensile stress induced in some parts of a structure.

The process of fatigue may be considered as consisting of three stages:
1) Initial fatigue damage leading to crack initiation.
2) Crack propagation until the remaining uncracked cross-section of a part becomes too weak to carry the loads imposed.
3) Final, sudden fracture of the remaining cross-section.

Stage (1) may be absent in components containing crack-like defects.

1.4.2 PREDICTION OF FATIGUE LIFE

In practice, prediction of the fatigue life of a material is

complicated because, except for a few relatively brittle materials, the fatigue life of a material is very sensitive to small changes in loading conditions, local stresses and local characteristics of the material. Because it is difficult to account for these minor changes in either the dynamic stress prediction techniques or in fatigue failure criteria, there is a large uncertainty inherent in analytical prediction of fatigue life. Thus the designer also is required to rely on experience with similar parts and eventually on qualification testing of prototype or production parts. Although laboratory fatigue tests performed on small specimens are not sufficient for precisely establishing the fatigue life of a part, it is useful to examine these data because laboratory tests (a) are the major source of fatigue failure criteria, (b) are useful in rating materials in terms of their relative resistance to fatigue, and (c) can be used to establish the relative importance of such items as fabrication method, surface finish, heat treatment, assembly technique and environment on the fatigue life.

In general, fatigue life can be expected to depend on the following parameters [21]:

1) Type of loading (uniaxial, bending, torsional)

2) Shape of loading curve

3) Frequency of load cycling

4) Loading pattern (periodic loading at constant or variable amplitude, programmed loading or random loading)

5) Magnitude of stresses

6) Part size

7) Fabrication method and surface roughness

8) Operating temperature

9) Operating atmosphere.

Traditionally, fatigue life has been expressed as the total number of stress cycles required for a fatigue crack to be initiated and then to grow large enough to produce catastrophic failure. Fatigue data also can be expressed in terms of crack growth rate. After the advent of better methods for crack detection, it was discovered that the cracks develop early in the fatigue life of the material and grow continuously until catastrophic failure occurs. This discovery has led to the use of crack-growth rates for prediction of fatigue life, the subject of Fracture Mechanics.

In operation, lifting chains used for hoisting and conveying, are usually subjected to variations with different loading values. Under these conditions, the fracture may occur at one or rarely two of the following positions: crown, transitions or weld.

Some of the parameters mentioned above such as loading frequency, loading pattern and surface roughness were investigated by Metz [22] using high-tensile lifting chain (A 7X21) complying with DIN 5684 [23], confirming their effect on the fatigue strength of chains. Furthermore, he reported that the effect of mean stress is irrelevant in the region of high stress range but as the stress ranges narrow, any change of mean stress has a more distinct effect on the fatigue life. The effect of mean stress was, however, far less than that caused by a comparable change in stress range. In his tests 99 % of the fractures occurred directly adjacent the welding seams, the remainder occurring in the transition zone.

Long link chains possess higher fatigue strength than those of short link chains; by contrast, an increase in link width decreases fatigue strength [1].

Although it has been reported (Bahke [3], quoting Wellinger [1]) that an increase in the tensile strength of a C-Mn steel chain by heat treatment caused an increase in the life at high stresses without a corresponding increase in fatigue limit (or possibly even a decrease), the chains compared had slightly different link shapes. Under these circumstances, one can regard this as only an isolated and rather ambiguous piece of information. Wellinger's results did, however, generally indicate that the fatigue strength of chains was fairly insensitive to the material's tensile strength. The chains were not calibrated.

Finally, some marked improvements in fatigue strength of short link chains can be produced either by dry rumbling or surface grinding, i.e. improving surface finish [24,25].

1.5 RESIDUAL STRESSES

1.5.1 GENERAL

Residual stresses are defined as stresses, which can exist in an elastic body, when it is free from external forces. They are sometimes referred to as internal or locked-in stresses. They are caused by mis-match between parts of the body that have been forced either by heat, transformation or mechanical working to expand or contract in a different way from the rest of the body and, in order to keep all these parts in a continuous whole, forces are needed between the various parts, and these constitute the internal stresses.

Residual stresses can be divided into two types, macroscopic and microscopic stresses. Microscopic stresses act over dimensions as

small as several unit cells, although their effect may extend through
most of a grain: they are caused by structural inhomogeneties, which
can also give rise to internal stresses even under macroscopically
uniform deformation, or changes in temperature. Macroscopic stresses,
on the other hand, vary continuously through the volume of the body
and act over regions which are large compared with atomic dimensions.
They can result from mechanical and thermal operations performed on
the body. The macroscopic stresses, which originate directly from
non-uniform plastic flow, as in the calibration of chains, have been a
principal area of investigation in the present work.

1.5.2 EFFECT OF RESIDUAL STRESSES

Residual stresses may have a beneficial as well as a deleterious .
effect. When the residual stresses are of an unfavourable type
(tensile at surface) they result in lowered yield and tensile
strengths and lowered fatigue strength. Residual stresses are also
responsible for warping during machining, quench cracks, season cracks
and grinding cracks.

On the other hand, when the stresses are favourably distributed, i.e.
compressive at the surface, they increase the fatigue strength of the
materials, and are therefore intentionally produced by, for example,
extrusion, forging operations, calibration of chains etc. This gives
the possibility of using residual stresses to produce components with
improved properties.

1.5.3 DETERMINATION OF RESIDUAL STRESSES

In view of their importance, it is not surprising that there has been

a continuing interest in developing methods for measuring residual stresses [26,27,28,29]. Since research effort first became directed at residual stress distributions, virtually every conceivable method of monitoring displacements has been employed.These can be classified into the following groups:

a) Mechanical: by necessity all mechanical techniques involve some degree of destruction; most experimental techniques have been based on the monitoring displacement over a defined gauge length, while physically relieving the locked-in stresses around the gauge by saw cutting, slicing, drilling or trepanning. The hole boring method [30] is also a mechanical technique.

The strains resulting from the relief of the locked-in stresses.are usually measured by resistance gauges. The theory of elasticity is then used to relate the measured strains to the pre-existing residual stresses.

Moire'; fringe-methods'or holography have also been proposed for strain measurement in place of resistance gauges.

b) X-ray and neutron diffraction (Chapter 4): have been applied to the task of measuring stresses in crystalline materials for some considerable time. The x-ray method is capable of measuring only surface stresses while neutrons because of their greater penetrations, can be used to measure residual stresses within a component. Both methods are nondestructive.

c) Ultrasonic [26,31,32]: several approaches have been attempted, all relying on the anisotropy created by a change in stress state. The

method is nondestructive but has not yet been developed as a reliable routine method.

e) Magneto-elastic [26,33]: utilises the dependence of magnetic flux density in ferromagnetic materials on the applied stress state. The obvious advantage is nondestructive nature and apparent simplicity.

f) Analytical (computational) [26,34,35,36]: one,two, and three dimensional programmes have been developed (finite element method), and some experimental verification has been attempted (Chapters 6, 7, and 8).

1.6 FINITE ELEMENT METHOD

1.6.1 FINITE ELEMENT SYSTEMS

Development and application of digital computers have accelerated the development of numerical techniques, finite element, finite difference and boundary element. Finite Element Method (FEM) being firmly established as a general numerical method for the solution of partial differential equation system, subjected to known boundary and initial conditions, is the most powerful numerical technique. In essence, the method by a process of discretisation describes the overall behaviour of a continuum by a number of subregions or elements. Each element is connected to its neighbours by nodal points, Fig. 1.2. The behaviour and characteristics of individual elements are derived independently of each other in terms of certain parameters at the nodal points of each element. Complications due to specifications of arbitary loading, geometry, and boundary conditions disappear and different and possibly complex constitutive relationships for each element are

easily allocated.

Over the past decade or so, finite element analysis has evolved from a technique for large structural analysis to a tool available and familiar, to some extent, to most engineers. Software and hardware developments have reduced costs and finite element analysis is now viable even for small jobs. Nowadays, a large number of finite element systems (packages or codes) exist. At one extreme are large general purpose packages such as NASTRAN, ABAQUS, PAFEC and ASAS, each with its own strength and weaknesses, and at the other extreme, are micro-based packages such as SESAM for off-shore applications and BERSAFE for pressure vessels. The details of specific packages are outside the scope of this work and can be referred to the Finite Element Systems Handbook [37].

For the finite element analysis part of this research, ABAQUS finite element (FE) software at the Manchester Regional Computing Centre was used. ABAQUS is one of the most powerful nonlinear packages available and its capability and method of use are contained in the updated manuals of the package [38,39,40]. In the initial stages of the research PAFEC [41,42] was used, but all the results in this thesis were obtained by using ABAQUS.

1.6.2 FINITE ELEMENT ANALYSIS OF CHAINS

The finite element method was first applied into chains by SDRC [43] to study design modifications to the 14 mm diameter wheel chain links. They considered two alternative geometries to that of the standard chain links, namely; pinched at the centre; shaved, that is with material removed from the outside of the barrel, and flattened leg

(oval cross-section), Fig. 1.3. The objective of their design study was to determine if such changes in the standard link geometry would reduce the high tensile stress in the shoulder where fatigue failures generally occured. Elastic beam analysis of the link geometries was carried out following three-dimensional stress analysis. The load was applied by a point load at the crown and the overall conclusions were:

1) The standard link configuration is the optimum geoemtry to minimize the inner surface tensile stresses at the shoulder.

2) The pinched (eight shape) design is stiffer than the standard link design.

3) The shaved design does not appear to offer a significant advantage over the standard design. In addition, a point will be reached where the stresses in the barrel will exceed those in the shoulder as more material is removed from the cross-section.

4) The flattened leg (oval cross-section) provides a desirable means to reduce the shoulder stress without dramatically increasing the stress level in the leg.

Metz also reported stress distribution in the chain link using the finite element method [22], Fig. 1.4.

Further three-dimensional elastic finite element analysis of chains were taken up by Modlen [44,45,46] to investigate the effect of link geometry on strength of chains. Alternative link shapes were pinched and elliptical. The following conclusions were drawn. A change in the link geometry from pinched to elliptical causes a systematic change in the magnitude of the stresses under load. The most tensile principal stress always appears on the inside of the chain links, but its location moves away from the mid-plane towards the crown. At the same time, the overall extension of the chain under load increases;

i.e. the chain modulus increases. The results refer to links of a specific overall length made from wire rod of one diameter.

Modlen [45] also investigated the effect of link length (length of straight section) on the stress pattern at the exterior and interior of the chain links. It was reported that the tensile stress on the interior of the link decreases as link length increased but the stresses around the crown increase and the crown becomes the location of the largest tensile stresses.

In 1986, Mattheck et al [47,48] investigated the effect of wear between chain links on the stress concentration in chains using the finite element method and came up with a patented chain link.

The loading between chain links so far was assumed to be a point load. This assumption is only true at the onset of loading for chain links having perfect surfaces. As the loading increases the chain links deform elastically and then plastically at the crown and the loading is no longer a point load. Ideally, a three-dimensional contact analysis of the chain links needs to be carried out to determine the contact area and contact pressure envelope. At the present, there does not appear to be a finite element code able to achieve this task and to develop one capable of this analysis was outside the scope of this research. Hence, an approximate contact area and contact pressure envelope was sought in the present work to give the required nominal stress at the cross-section due to the loading.

1.7 OBJECTIVES AND LAYOUT OF THE THESIS

The main objectives of this study are:

1) To investigate the effect of link geometry on the total and residual stress patterns in mining and lifting chains using FEM.

2) To evaluate the changes in residual stresses due to increase in calibration loads for mining and lifting chains using FEM.

3) To verify the total and residual stresses obtained in (1) and (2) using the strain gauge, x-ray and neutron diffraction techniques.

4) To demonstrate the effect of calibration on fatigue strength of lifting chains.

Manufacture of round steel chain for lifting and mining purposes will be described in Chapter 2 with all the required testing procedures according to the British Standards. Fatigue testing of 7mm lifting chains will be covered in Chapter 3 with the statistical interpretation of the results. The effect of increase in calibration load in the fatigue strength of this grade of chains are also illustrated with S-N curves and cumulative curves for the probability of fracture. The rest of the experimental work involves the measurement of the total and residual stresses in the 19 mm mining and 7 mm lifting chains. The x-ray and neutron diffraction techniques were used for both grades of chains under various calibration loads and the experimental procedure and results will be presented in Chapter 4. The strain gauge method of total and residual stress measurement was used only for the mining chains (due to size limits) with various geometries, namely, oval cross-section, eight shape (pinched), standard and elliptical chain links under various calibration loads. The procedure and results will be given in Chapter 5.

The effect of link geometry on the total and residual stresses was

investigated in mining and lifting chains using the finite element method in one, two and three dimensions. An elasto-plastic material model will be used with work hardening. As the chains undergo a large deformations under loading a complete geometrically nonlinear analysis will be carried out with required material model (elastic or elasto-plastic) in one, two, and three-dimensional analysis of chains (Chapters 6, 7 and 8).

The residual stresses in chains as a result of pre-loading (calibration) will be found by taking the finite element models of chains through a loading-unloading cycle.

Beam analysis (one dimensional) of the chains will be introduced in Chapter 6. The load will be applied over one element at the crown to produce an elliptical pressure envelope and to avoid numerical difficulties at the crown (Chapter 6).

The two-dimensional contact stress analysis of the chains will be carried out in Chapter 7. The contact area and contact pressure envelope obtained from this analysis was incorporated in the three dimensional assumption of the contact pressure envelope.

A complete three dimensional stress analysis of the chains was carried out and the results will be discussed in Chapter 8. Finally, discussions, conclusions and suggestions for further work will be given in Chapter 9 and 10 respectively.

CHAPTER 2

MANUFACTURE OF ROUND-STEEL LINK CHAINS

2.1 INTRODUCTION

Round steel link chains have extremely wide ranging applications and only hoist (lifting) and mining chains will be considered here. The manufacturing processes used for these chains are quite similar.

The strength of chains remained fairly constant based upon mean stresses of 200 - 300 MPa up to the mid - 1940's. They were manufactured from wrought iron or mild steel. The period 1950 - 1970 saw the introduction of carbon steel and later, alloy steel chains with increasing strength levels up to 800 MPa, which is the present day norm. There is also grade D quality mining chain operating at 1000 MPa [49].

The art of chain manufacture is to produce the finished link dimensions and mechanical properties specified by the customer while ensuring that the resulting chain will perform satisfactorily in service. It has been found that the selection of raw material and its heat treatment play a vital role in obtaining such a chain (Sections 2.2 and 2.5). Hence, a balance must be struck between heat treatment and calibration which will minimize the problems in service (Section 2.6). Once the degree of calibration is established the various intermediate link shapes can be deduced. This deduction cannot be based purely on calibration since, in addition to the predicted geometrical changes, the finished link is always longer and narrower than the welded link, which in turn is shorter than the formed link due to upsetting during welding. The formed link dimensions having been established, the kingpost around which each link is formed can be machined. All this information together with details of raw material, manufacturing tolerances and mechanical properties are tabulated in a

basic chain sheet, Fig. 2.1. Quality and operational reliability of the round link steel chains depend above all on the preciseness of each separate operation such as the reliability of the systems of testing, heat treatment, inspection, etc. In this chapter these separate operations will be discussed in details.

2.2 INITIAL EXAMINATION AND RAW MATERIAL SELECTION

The selection of the material for round link chain is made according to the works directive and appropriate British Standards. Traditionally alloy steels of the Ni, Cr, Mo type have been used for high strength chains. Mining chain specifications leave the choice of steel to the manufacturer, applying certain provisos related to the content of sulphur, phosphorus and aluminium and to the grain size. The material having been selected, the initial examinations ought to be carried out before starting other manufacturing processes.

2.2.1 INITIAL EXAMINATION OF THE RAW MATERIAL

In order to ensure efficient chain manufacture and prevent any confusion or mistakes in the material supplied, chain manufacturers increasingly carry out spot tests despite the availability of the works test certificate. The starting material (cold drawn, hot rolled or annealed) is chemically and physically analysed, its tensile strength, elongation, carbon content and hardness values are determined, and where necessary, its heat treatment characteristic are investigated. In some circumstances a cold bending test is also applied.

Prior to forming, surface condition and dimensional accuracy must also

be checked and, where necessary, the steel surface must be cleaned off all non-metallic material in particular of the oxides (FeO, Fe_3O_4, Fe_2O_3). Descaling can be achieved by various methods, like pickling with sulphuric acid [50] and drawing through a die to straighten the coiled material (Fig. 2.2).

2.2.2 RAW MATERIAL SELECTION

High tensile steel chains are produced almost exclusively from electric steel. They are made of low alloy manganese, chromium manganese or boron steel. When considering steel composition to be used several factors must be considered:

a) Response to heat treatment - the required mechanical properties such as hardenability, ductility and toughness must be achieved for the chain size after the hardening and tempering to the desired strength level.

b) Weldability - for the steel selected, the requirement of good weldability places a restriction upon the total alloying addition to be made, and particularly on the carbon content.

c) Formability - larger link sizes are normally hot formed at a temperature close to 800° C, where the steel will be highly ductile and inherent formability of the material is unimportant. Smaller link sizes are, however, formed at room temperature and the material must be sufficiently ductile to allow this. For this reason drawn and annealed wire or rod must be used

d) Grain size - material in the finished link must have fine grain

size to achieve optimum combination of strength and toughness. This
is usually ensured by the use of aluminium killed steels.

e) Steel cleanness - inclusion content of steel must be kept to
minimum. The inclusions in the weld region become transversely
aligned and can exert significant stress-raising effects.

2.2.3 STEEL TYPES IN CHAIN MANUFACTURE

Steels used in round link high tensile chain manufacture are
        alloy (low and high) and boron steel and a brief description
is given below for each type.

a) Alloy steel - low alloy and case hardening steels are used ·almost
exclusively in the manufacture of high tensile chains. Because of the
larger contents of Mn ($\geq$.6) and Si ($\geq$.1) and partly because of the
presence of alloying constituents such as Cr and Ni, the properties of
the material such as tensile strength, yield point, elongation, wear
resistance, notch impact strength, etc. are greatly modified. It
should be pointed out that in practice a whole series of materials is
used of different composition in accordance with the desired
properties of the finished product. Plumbridge et al[51] investigated
one of these materials, which is similar in chemical composition to
the material used in this research.

The chemical composition of the steel used for manufacture of the 19
mm mining chain is : carbon .2-.25 %, silicon .2-.35 %, sulphur .015
% max., phosphorus .015 % max., manganese 1.2-1.5 %, nickel .95-1.3 %,
chromium .45-.65 %, molybdenum .5-.6 %, aluminium .02-.05 % and copper
.25 % max.

Mining chains are used in flight bar assembly, Fig. 2.3, to convey the coal from the mine face.

b) Boron steel - there are numerous technical papers [52,53,54,55,...] concerning the application of boron as an additive to commercial steels together with the 'rules' that researchers have revealed. The fact that hardenability of steel is enhanced by the addition of boron makes it a potential candidate in chain manufacture. Here, a review of the some of the properties of the boron-treated steel as a chain material for use as a grade T (80) (mean stress at specified minimum breaking load is 800 MPa) lifting chain [14] is given in comparison with low alloy steel (SAE 8622).

I) Chemical composition - boron is becoming an increasingly popular addition for fine grained low and medium carbon alloy steels to increase their hardenabilities. The mechanism of this effect is generally agreed to be the segregation of elemental boron at prior austenite grain bounderies, which causes the suppression of the ferrite, transformation and thus improves the hardenability. In order to ensure that this mechanism occurs the boron must be in a soluble form and, therefore, be protected with aluminium deoxidation. The amount of boron must be about .001 % and .004 % maximum.

The chemical composition of the steel used in manufacture of the 7 mm lifting chain used in this research is : carbon .18-.23 %, silicon .15-.35 %, sulphur .025 % max., phosphorus .025 % max., manganese .70-1.0 %, chromium .15-.3 %, nickel .40-.60 %, aluminium .02-.05 %, copper .25 % max. and boron .001- .003 %.

II) Hardenability - in the research carried out by Potts and Metha

[55,56], it was shown that the boron-treated steel has greater hardenability than the low alloy steel (SAE 8622) and equivalent hardenability to DIN 1.6542 (German specifications).

III) Temper resistance - boron-treated steel has significantly better toughness characteristics than the SAE 8622 material [55]. The work by King et al [57] and British Steel [58] also show good toughness and strength throughout the tempering temperature range up to 400° C.

IV) Low temperature impact properties - the results of the low temperature Charpy impact properties [55] show that, over the range -20° to 20° C, the boron-treated steel exhibits superior toughness properties compared with those of SAE 8622.

V) Chain tests - analysis of production quality tests indicate that at the required strength level, elongations are in excess of 20 % [59] and improvements on the previous SAE 8622 production which gave typically 17 % (BS4942).

On the whole, the boron-treated alloy steel exhibits excellent properties, generally superior to those of the low alloy steel SAE 8622.

Lifting chains of different sizes are used in various lifting tackles shown in Fig. 2.4.

2.3 FORMING

Pre-bending of the individual links may be either hot or cold. It depends upon the material diameter and its strength. The material is

cold formed up to about 20 mm diameter in size and pre-heated for larger diameters, Fig. 2.5. The material to be bent is sometimes lubricated with cutting oil in order to avoid damage to the material during bending and eliminate marks on the bent chain link while minimising wear between tool and material in order to prolong the working life of the tool.

The forming of the links prior to welding is carried out either mechanically or hydraulically. The simplex and duplex bending methods [50] are the two main mechanical bending methods. In simplex method, the wire is cut and formed around the kingpost at the operating station, while in the duplex method, the forming is carried out in two (pre-bending and finished bending) operating stations. The duplex bending method is therefore approximately 50 % more efficient.

The exact bending is very important for all the following production steps, because it provides the basis for the dimensional and mechanical properties of the finished chain. The definitive form, the final dimensions and the calibration force necessary to pull the chain to the final dimensions, are established mainly in this process.

2.4 WELDING (BUTT AND BUTT FLASH)

Either the butt or flush butt welding process is used, depending on the wire diameter and quality required. The important features of both methods are given in a table, Fig. 2.6 [60,61].

Butt welding offers shorter weld times; it is very clean with low material consumption and tighter bending tolerances to obtain a better weld. Its application range extends up to 20 mm wire diameter. Flash

butt welding requires longer weld times, produces undesirable welding splashes and consumes more material in upsetting and flashes, but less stringent bending tolerances and wire quality are needed. It is economical from about 13 mm diameters upwards.

2.4.1 BENT LINK SHAPE FOR BUTT AND BUTT FLASH WELDING

For butt welding, the chain links are bent cold and the welding gap is chiplessly formed by notching before the link lengths are cropped. Bending tolerances must be very close to ensure high quality chains in demand nowadays. Hence drawn and annealed stock is mainly used, which also gives clean contact surfaces for the electrodes, Fig.2.7a. For flash butt welding, the chain links are bent cold or, for higher tensile grades, hot from about 22 mm diameter up. The heating.of the stock blanks for bending is done by resistance or induction heating, Fig. 2.5. The flat cut end is sufficient for the welding gap. Rolled material of appropriate tolerance and finish is normaly adequate for flash butt welding, as wider chain bending tolerances are acceptable for this process, Fig 2.7b.

2.4.2 BUTT WELDING PROCESS

The situation at the start of the butt welding is shown in Fig. 2.8a. The upsetting tools, which apply the necessary pressure during welding, press against the chain links bows. The saddle supports the back of the links while the two electrode pairs are clamped on the chain link legs to be welded. The upsetting tools advance to make a contact at the weld joint the current is switched on, which is divided into the shuntback and the proper weld current. The necessary weld pressure is applied by the upsetting tools. The advance is controlled

mechanically by a cam, so that a relatively simple welding is obtained.

The butt welding is three times as fast as flash butt welding, requiring high currents. The electrode contact surface is strictly limited by the chain geometry, a situation which becomes highly unfavourable with larger diameters.

2.4.3 FLASH BUTT WELDING PROCESS

The situation at the start of the flash butt weld is shown in Fig. 2.8b. The total tool system is very similar to that for butt welding, the difference lies in the flat ends of the weld joint, which is open at the start. The upsetting pressure is provided by the upsetting tool. The flash butt welding process is controlled by regulating system developed by the advances in hydraulics and electronic. It can be divided into three stages:

a) Reversal for pre-heating the weld joint - the regulating systems controls the current, the amount of contact pressure and the time to heat the open ends to achieve the required temperature.

b) Flashing - starts after the completion of the reversal phase with the open ends approaching each other slowly while the welding gap is open and the current is on.

c) Upsetting - after flashing, the upsetting is initiated by increasing the tool approach speed, the current being switched off during the upsetting and the welding is complete.

Butt welding machines are controlled mechanically by cam with additional elements, such as springs and pneumatics used for upsetting tools and electrodes. After welding, the weld flash is removed by trimming cutters working in directions opposed to each other. Fig. 2.9 shows the work station with electrodes, saddle and retracted flash trimming blade. The machines cope with chains of up to 2 - 20 mm diameter.

Flash butt welding machines handle all grades of chain in the range from 13 - 40 mm diameter. The machine operation is fully hydraulic. In the same work station, having been once clamped the chain links are welded and fully deburred. The working station is fully open to avoid problems from flashing slag, Fig. 2.10.

2.5 HEAT TREATMENT OF CHAINS

The heat treatment of chains is not laid down in the British Standards ,and only reference to mechanical properties are made, but how these are obtained is left to the manufacturer.

There are standard furnaces for heat treatment of round steel chains. These include furnaces with fuel firing, electric heating (resistance), combined heating, gas/electricity or oil/electricity and specially designed induction furnaces.

a) Standard furnaces with fuel firing - these furnaces have been used for decades, Fig 2.11 [62], and there are four types according to the chain steel diameter and throughput, mainly for austenizing processes. In these furnaces, the continuous chains are surrounded by burner flames, avoiding direct flame contact,and are heated by radiation and

convection. After achieving required temperature, the chains ,
singular or multi-stranded according to the diameter, are quenched and
conveyed by the reeling device to the outside and left to cool in the
open.

The design of the furnace is set by the requirements of the hardening
process. There are two important factors to be considered here:
heating time and throughput speed - a lower throughput speeds results
in incorrect quenching, i.e. the chain cools above the quenching
tank.

b) Standard furnaces with electrical heating - this furnace has the
advantage of good temperature uniformity and is mainly used for the
hardening process. Similar varieties in size as in fuel firing
furnaces exist with the advantage of no over pressure. The heating in
these furnaces is provided by the filaments in the form of rings,
arranged along the whole height of the furnace. They are often more
costly than the fuel firing furnaces [62]. Finally, they have cleaner
environment - no possibility of pollution as in the case of fuel
firing furnaces.

c) Standard furnaces with combined heating, gas/electricity or
oil/electricity - these furnaces have been developed to combine the
low energy cost of fuel firing furnaces with better temperature
uniformity of electric furnaces. The main energy requirements is
covered by the fuel firing part and electrically heated discharge part
provides for the desired temperature uniformity needed in the heat
treatment of high strength chains.

d) Induction furnaces – electrical induction heating has simplified many heat-treating operations. Small parts can be through-heated and hardened as in other type of furnaces. Local or selective hardening, as well as surface hardening, is possible at a very rapid production rate. Furthermore, a standard induction unit can be adapted to a wide variety of products by simply changing the induction coil and adjusting the equipment settings. Continuous induction hardening has been in use since 1960, and has progressively replaced gas-fired hardening to the point where induction is now used exclusively. Until recently, however, tempering has been a batch operation, with a floor to floor time of about 10.5 hours for total heat treatment. For heat treatment of chains Wheway Becker Ltd. [63,64] have developed a plant which enables as-welded chains to be continuously hardened and tempered, Fig. 2. 12a and 2. 12b. It consists of three coils in line:

Coil A – the chain is hardened by passing it through a solenoidal wound induction heating coil. The heating of the chain above the Curie Point of 768° C ensures an even heat distribution around the link and on quenching from 900° C into water, a uniform hardness of 500 BHN is achieved around each link.

Coil B – The chain is then passed through an homogenising coil. A series of coils wound in a unique manner result in a uniform tempering of the chains. The actual hardness achieved can be controlled by the power input and may be varied accordingly to the service application.

Coil C – the third coil is again solenoidal but of a different design for the hardening coil. This coil tempers the parallel sides of the link whilst leaving the crowns of the link at higher hardness level.

Again the power input can be varied to control the hardness of the side barrels according to the operational requirements.

The net effect of heat treatment plant is therefore to produce a chain with a high crown hardness, giving improved wear resistance, greater toughness, greater resistance to stress corrosion cracking, greater breaking load, lower residual stress levels in the link, larger service life, greater reliability and finally competitive price [63]. The chains used in this research had uniform properties.

e) Tempering furnaces - in most cases chains are tempered in shaft circulating furnaces. The chains are hung onto a rack which is then inserted into the furnaces. Chains can also be tempered using continuous process, i.e. the ascending and descending channels are heated. The built in ventilators provide the necessary circulation speed and gives an optimal temperature uniformity.

2.6 CALIBRATION

During manufacture each heat treated round steel chain link is loaded with the prescribed test force, so that the weld is tested. During this process every chainlink is deformed plastically: the single links are adjusted to the measurements in the standard specifications. This process is called 'calibration'. For this purpose fully automated calibrating machines are used. Calibration load can be adjusted precisely and each calibrating stroke can be shown on a measuring tape or digitally. Afterwards, the chain will subsequently behave elastically up to the calibration load: that is , the yield is raised. This increase in yield results in introduction of residual stresses into the chain improving its fatigue properties (Chapter 3).

If fracture occurs at or below the specified test force, the chain must be rejected. After having been successfully calibrated, chains must be inspected on all sides visually link for link for imperfect welds, burnt spots or cracks. Fluorescent dye-penetrant and magnetic testing are also used for crack detection [65]. Faulty links are replaced with standard quality chain links, then heat treated and tested again. If the number of faulty links exceeds 3 %, the chain must be rejected.

2.7 MECHANICAL TESTINGS

All requirements such as dimensional accuracy, elongation at the test force, breaking force, elongation at fracture, deflection, notch toughness and the numbers of cycles to failure under a standard fatigue cycle of the sample are ascertained during the final control according to the appropriate British Standards. The dimensional and tensile tests are obligatory and other tests can be done in accordance to the customer's requirements. The chain characteristic curve is also determined to show the relationship between effective force and extension. The chains which pass the the required tests in all the production stages, have to be finally approved by the works inspector. Following final inspection, samples are taken from each production batch of chain and are subjected to mechanical testings as below:

a) Hardness testing - is carried out onto flat ground onto the surface of a single link from each batch of chains to confirm the heat treatment has been carried out correctly.

b) Bend test - individual links are bent in a shock force manner transversely across the weld and must withstand a miminum deflection

without failure or appearance of surface flaws, Fig. 2.13. The deflection is usually measured with the bending force applied.

c) Notch-impact Charpy test – this test is intended for use in the investigation of the steel used for chain making and assesses the properties of steel using samples machined from the core of the straight legs of each sample link. The test is Charpy U notch and carried out at room temperature.

d) Tensile test – a sample of five or seven links is tested in a certified testing machine, Fig. 2.14a and 2.14b. The failure is pure "shear" failure [66].

e) Fatigue test – a sample of chain is subjected to cyclic loading between lower and upper tensile force limits and its fatigue life is found. This process will be covered in full details in Chapter 3.

2.8 SURFACE PROTECTION

In most cases steel chains are used in nature-black condition: for some application bright type is usual. After a short time the atmospheric influences cause the formation of a rust on the surface. By suitable protective coatings this rust formation can be prevented for a longer period of time.

As a protection during transport and as a preservative for longer storage various corrosion preventives proved effective. Coats of varnish and plastic-laminates form sufficient protection for a limited time, as long as the protective covering is not partially destroyed by external mechanical actions.

Chains with a bright surface are best protected by electroplated zinc, brass, copper, nickel, or chromium coatings. Often an intensive oiling or lubrication of the chain would be efficient. Hot galvanising forms a good protection against corrosion for thicker chains [67].

CHAPTER 3

FATIGUE TESTING OF 7 mm LIFTING CHAINS

3.1 INTRODUCTION

Fatigue usually starts by the formation of a crack at the surface and anything which makes crack initiation easier - e.g. decarburization, surface roughness, etc. will reduce fatigue life. Heat treated ferrous materials often have lower fatigue strength than expected because of inferior surface properties or poor surface finish. They can however be improved by removing the surface layer. For example, Foley et al succeeded in improving the fatigue strength of short link mining chains by dry rumbling and wet grinding [24]. Batson and Bradley ([68], quoted in [24]), significantly improved the performance of steel springs by the grinding surface. The reduction in fatigue strength was attributed by these workers to decarburization. The surface decarburization process was investigated and three distict features were postulated:

a) A reduction in the carbon content of the surface layer produces an inherently weaker material which would fail under lower cyclic stresses.

b) Surface roughness accompanying decarburisation contributes to the lowering of the fatigue strength.

c) Grain boundary oxidation in the surface layer acts in a similar manner to notches and is often the principal factor in the reduction of the fatigue strength of decarburized steel.

Once the grain boundary oxidation has occurred, nothing short of re-melting will remedy the situation fully. Some improvement in fatigue strength under tensile loading can be obtained, however, by

introducing residual compressive stresses into the decarburized layer, by surface hardening, nitriding, case hardening and shot peening. These techniques are described more fully by [29,69]. Surface hardening was recommended by Minuth et al [70] for the mining chains failing in fatigue (corrosion cracking) under surface frictions.

It is suggested that the hardness of the core of a specimen has a lesser effect upon fatigue strength than does the hardness of the decarburized layer. The effect of the depth of the decarburized layer on the fatigue strength of steels has also been investigated by several researchers and the results are quite varied; a continual decrease in fatigue strength with increase in decarburized depth has been reported with notch specimens, on the other hand, the depth of the decarburized layer was found to have no significant effect whatsoever, but the reduction in fatigue strength depended on the microstructure of the material before carburization [24]. The reduction in the fatigue limit was found to be 30 %, 40 % and 50 % for pearlite, tempered martensite, and martensite respectively [24].

Overstressing of pressure vessels has long been applied as an inspection tool to detect any leakage in the wall and to demonstrate the fitness for purpose of the vessel. It was found that overstressing improves the fatigue life by delaying crack growth [71]. The study on notched aluminium alloy sheets showed that the overloading of specimens produced similar beneficial effects by delaying the crack growth [72,73]. Preloading - generally known as proof or calibration loading - also improves the fatigue strength of stud links up to some extent [74] and short link chains significantly [75]. This will be thoroughly investigated in this chapter.

Most of the fatigue data in the literature have been determined for 'condition of completely reversed cycles of stress (zero mean stress). However, conditions are frequently met in engineering practice where the stress situation consists of an alternating stress and a superimposed mean stress. There are several possible methods of determining S-N curve for a situation where the mean stress is not equal to zero [76]. Early contributions to this problem were made by Goodman, so that the curves which show the dependence of limiting range of stresses on mean stresses are frequently called Goodman diagrams. Fig. 3.1 shows one common type of Goodman diagram [76,77] which can be constructed by a series of tests for a given material. Basically, the diagram shows the variation of the limiting range of stress, $(\sigma_{max} - \sigma_{min})$, with mean stress, σ_m. The test data usually lie somewhat above and below the σ_{max} and σ_{min} lines respectively. Very few test data exist for the condition where the mean stress is compressive. Data [78] for SAE 4340 (quoted in [76]) steel tested in axial fatigue indicate that the allowable stress range increases with increasing compressive mean stress and decreases with increasing tensile mean stress up to the yield stress (σ_y). This is an agreement with the fact that compressive residual stresses increase the fatigue limit.

In this chapter, the fatigue testing procedure with its results will be discussed for various calibration loads and two different batches of chains, Section 3.2 and 3.3. The failure analysis of fatigue tests will be described with the use of electron scanning microscopy in Section 3.4. Other mechanical testing of the chains such as, hardness testing with metallography will be presented in Section 3.5. Finally, the effect of mean stress on fatigue strength of chains will be elaborated using a Goodman diagram approach.

3.2 FATIGUE TESTING PROCEDURE

The short link chains used in this investigation are made from 7 mm
diameter bars (R_1 = 5.55, R_2 = 3.45, L = 5.45 mm, Fig. 1.3)
manufactured from boron steel with the chemical composition given in
Chapter 2 and are used for lifting purposes, BS3243:4:1

The chain was in the hardened and tempered condition with no proof
loading before testing.

Fatigue tests were carried out on a 250 kN Mayes servohydraulic
machine that is capable of generating the required sinusoidal signal
with an appropriate number of cycles per minute (rate of testing),
Fig. 3.2. For all the tests, 500 cycles per minute was chosen to
eliminate any possible effect due to rate of testing.   Foly et al
[24,25,75], Celander et al [74] and Stanford [79] used 2000, 850 and
200 cycles per minute in their work respectively. Meanwhile for the
mining chains, the frequency ought to be in the range of 200 to 1000
cycles per minute, BS2969. The chain links were tested in three-link
sets released from a continuous batch of a chain supplied by Wheway
Becker Ltd. [80]. The sample was held in the machine by specially
designed grips, shown in Fig. 3.3, with a pair of chain crowns cut
and filed to simulate the real contact situation between the links
rather than a pin through the links chosen by some researchers.

It is not possible to test under conditions of zero mean load, as is
the norm with fatigue testing, since the links would go slack during
the nominally compression part of each cycle.   Furthermore, it was
found that it was extremely difficult to set the machine to test under

conditions of zero minimum load. Hence, all the tests were conducted with a minimum load of 2 kN, the maximum load being varied for the test condition required, 12 - 24 kN.

The links were either tested to failure or until they reached two million cycles, at which stage the test was terminated and the links were considered to have survived. The fatigue lives of the specimens failing under two million cycles were recorded by the use of fracture trip facility on the testing machine.

To calibrate the specimens, they were first positioned in the machine and the load was raised up to the required level and sustained for a few seconds before unloading.

3.3 FATIGUE TESTING RESULTS

The fatigue tests were carried out with load ranges from 2 -24 kN down to 2 - 12 kN (the working load limit for this grade of chains is 16 kN) to study the scatter of results at various load levels and different calibration loads. The results are given in Table 3.1 showing the location of failure as well as end or centre link failure for a given batch.

A considerable amount of interest has been shown in the statistical analysis of fatigue data and in the reasons for the variability in fatigue test results. Since fatigue life and fatigue limit are statistical quantities, it must be realised that considerable deviation from an average curve determined with only a few specimens is to be expected. This will be thoroughly investigated in the next section using cumulative probability curves.

The basic method of presenting engineering fatigue data is by means of the S-N curves, a plot of stress against the number of cycles to failure N.   A log scale is almost always used for N especially in the case of N $\geq 10^4$. This method will be used later to explain the fatigue test results of 7 mm lifting chains.

3.3.1 STATISTICAL PRESENTATION OF RESULTS

There are various statistical distribution functions which describe the distributuion of fatigue life at constant stress, such as: Weibull and Gaussian or normal distribution [81,82,83].   The normal distribution was used here because of simplicity and its common use in fatigue life analysis of chains (BS2969).

In this distribution, the fatigue results are plotted on a diagram with:

a) On one scale - the number of cycles to fracture (endurance) of the
   individual samples (logarithmic scale), i.e. log N :

b) On the other scale - the probability of fracture of the sample,
   i.e., the percentage of samples having an endurance less than log N
   (Gaussian cumulative).

   - the number of cycles is ranked and plotted on the ordinate

   - the probability of the fracture on the abscissa using the formula

   i/(n + 1);

   where   i = the ranked value of the sample

           n = the total number of tests

n was 10 except for load level of 16 kN when the calibration load was zero (n=20). The samples which survived the test will not be included in the plots. The best line is fitted to these points, Fig. 3.4 to

3.9. The shape of the line is a measure of the dispersion of the
results, a horizontal line indicating zero dispersion. The fact that
a good straight line is obtained indicates that the assumption that
log N is normally distributed is consistent with the experimental
results.

From these plots it can be seen that the new batch has a much lower
fatigue life. This will be elaborated in the next section. In all
the graphs as the calibration load increases, the fatigue life also
increases, confirming the effect of increased calibration load on
fatigue life of chains. In Fig. 3.8, the logarithms of the means of
the lives of the uncalibrated and calibrated (20 kN) chains are not
significantly different. Application of the 't' test [84] showed that
the chance of getting a difference of the size or bigger is greater
than 30 %, that is, there is no significant difference between the
results for the uncalibrated chain and the chain calibrated at 20 kN.

3.3.2 S-N CURVES

The stress values used in the S-N curves are nominal stresses with no
adjustment made for stress concentration. Under general loading
condition, the stresses on a gross scale are elastic, but some parts
of chain may deform plastically in a highly localized way, specially
under loads around 30 kN and over. Hence, the fatigue testing is
high-cycle ($N > 10^5$) fatigue and the S-N curves can be
appropriately used to illustrate the fatigue results.

L_5, L_{20}, L_{50}, L_{80}, and L_{95} (L_5 being the
average life at which 5 % of the samples will have fractured) were
tabulated for all the fatigue test results in Section 3.3 and are then

plotted in the linear-log scale (S-N curve), Fig. 3.10 to 3.14. A smooth curve is drawn through the points, terminating at two million cycles due to the convention adopted earlier. Hence fatigue limit determination which is subject to considerable variation will not be attempted. It can be seen from the S-N curves that the increase in calibration load results in increase in fatigue life of 7 mm lifting chains. This effect is evident in all the S-N curves at the various probabilities of failure (5 - 95 %). It can be concluded that calibration of chains introduces compressive residual stresses (acting as mean stresses) which are deducted from the applied tensile stresses resulting in lower service stresses; consequently a significant improvement in fatigue life of chains is achieved.

3.4 ANALYSIS OF FATIGUE FAILURES

Fatigue fractures were examined by optical microscopy, which did not reveal any appreciable differences among the specimens. The eight specimens were then examined using electron scanning microscopy.

Fatigue cracks and fractures exhibit several features which can aid this recognition. Not all these features are present in any particular fracture but, in any individual case, consideration of these aspects can normally distinguish fatigue from other mechanism of failures [85,86]. These features are as follows:

general appearance
location of fracture
beach markings
rachet markings
fatigue striations

A typical chain fatigue fracture is given in Fig. 3.15, showing the final ductile fracture (rough zone) and a smooth appearance in the fatigue zone.

Fatigue failures often occur at regions of localized stress concentration, e.g. weld toes, changes in sections, an existing crack etc. Stress concentration zones in the chain link are at the crown (outside and inside surface) and the transition zone (inside surface) according to the elastic and elasto-plastic stress analysis (Chapters 6, 7 and 8). All the cracks initiated from the zones of largest stress concentration, except for some samples fracturing at the weld. In case of two samples, the cracks started from an existing dent, Fig. 3.16; Fig. 3.17 at the weld; and Fig 3.18 and 3.19 at the transition zone.

As the links were heat treated after the welding processes, the Heat Affected Zone (HAZ) was removed and the whole link has a uniform microstructure, Fig. 3.20 (a and b). The more reliable reason for fracture in the weld is most likely to be either because of stress concentration caused by the shape there. The steel being very clean the inclusions were unlikely to cause any stress concentration (Fig. 3.20a).

Fig. 3.21 shows the different location of fatigue failure, and Fig. 3.22 the locations of the fractures due to the tensile test and fatigue test.

Beach markings were observed, Fig. 3.16, Fig. 3.18 and Fig 3.19 which indicate that fatigue did not propagate continuously but in steps with intermediate pauses. Ratchet markings are shown in Fig. 3.17 which indicates that multiple crack initiation occurred.

There are a few other factors which may influence the fatigue fracture location such as:

effect of calibration load
load levels
different batches
whether the link was at the centre or the end of the three
tested links
To investigate this a statistical software Minitab [87] was used. The

fatigue results in Section 3.3 are presented in tabular and graphical

forms, Table 3.1 to 3.3 and Fig. 3.23 and 3.24. Fig. 3.23 indicates

that the percentage of fracture failures at weld zone does not change.

significantly with increase in calibration load, whereas, the

percentage of fractures at the crown and transition zones changes

considerably in the opposite direction (failures at the crown zone

increases and the transition zone decreases). Fracture appears to be

equally likely at centre and at end links. A similar pattern of

behaviour occurs with an increase in load level except that there is a

slight increase in the percentage of fracture occurring in the centre

link, Fig. 3.24.

Different batches of chain seem to have a great deal of influence in

the centre and end link failures, Fig. 3.25. It also affected the

fracture location significantly - 76 % of the samples failed at the

weld in the second batch (Fig. 3.25). In the earlier section, it was

mentioned that the second batch of chains had shorter fatigue lives.

This was combined with a higher rate of fracture at the weld. The

probable explanation is that the welds of the second batch were not

trimmed off totally as in the first batch. This may have caused local

stress concentration at the weld zone higher than the above mentioned

zones. Finally, the effect of centre or end links on the fracture

position is shown in Fig. 3.26, showing that there is only a small

difference in the percentages of the different fracture positions

between centre and end links.

3.5 MECHANICAL TESTING OF CHAIN MATERIAL

The tensile testing, hardness testing and metallography of the chain material was carried out on the as-received condition and the results are discussed below:

3.5.1 TENSILE TESTS

Tensile testing was carried out for two sets of specimens, namely welded and plain, prepared from the chain link material. Testing was carried out on a Hounsfield tensometer using specimen no. 12 (nominal cross- section, 1/40 in^2. [16.29 mm^2]; nominal gauge length, .632 in. [16.053 mm]). In addition to the ultimate tensile stress, reduction in area and percentage elongation, the yield point was approximated from the end of the initial elastic loading line.

The results indicate that the weld material has ductility as good as the parent material. There are indications from the few tests carried out that the welded specimens had slightly lower values of tensile and yield stresses. The average tensile and yield stresses for plain and welded specimens are 1394, 1191 and 1285,1104 MPa respectively, Table 3.4.

A tensile test on a five-link specimen was carried out on a Mayes machine and the load-extension curve is given in Fig. 3.27. The ultimate load (68.4 kN) is slightly higher than the manufacturer's value of 64.1 kN and the elongation percentage is 29.5 %. The load-extension curve departs from a straight line at about 30 kN and breaks off at an extension of 32.3 mm.

3.5.2 HARDNESS TESTS

The hardness of chain link at three cross-sections (crown, mid-section and transition) and one section through the weld along the side of the link, was found using a Vickers pyramid hardness machine. Specially prepared specimens used for metallography were used on this test and the corresponding readings were tabulated, Table 3.5. Only two sets of readings are given here due to the fact that the other readings were very similar.

The Rockwell hardness test was also carried out on the prepared specimens to confirm the hardnesses given by the manufacture and Vickers hardness machine. The following readings were obtained for two specimens: 37, 37 and 39 (average 38): and 30, 43 and 42 (average 38). The Rockwell hardness number is equivalent to 363 Brinell hardness number, which is in the range (360 - 400) of the values given by the manufacturer.

There was not any difference in hardness corresponding to the apparent difference in ultimate tensile stress between plain and welded tensile specimens.

3.5.3 METALLOGRAPHY

Metallography was carried out to evaluate any microstructural defects in the chain link under investigation.

Four specimens were selected: one from the crown, one from the transition , one from the weld, and lastly one from the leg containing the weld to check for the heat affected zone and signs of 'directionality'. All these specimens were prepared and viewed under the microscope with no significant difference between them. A typical

tempered martensitic crystal structure with rectangular and cuboid inclusions can be seen, Fig. 3.20 (a,b). Appreciable grain-boundary thickening is evident at the edge of the cross-section, Fig. 3.20 b. The heat affected zone around the weld could not be distinguished, because the chain was quenched and tempered after the welding processes (weld going horizontally through Fig. 3.20 a). It was scarcely possible to distiguish any features of the structure that would indicate the location of the weld.

3.6 EFFECT OF MEAN STRESS ON FATIGUE

The effect of mean stress on fatigue strength of various metals specially that of steels has been very well established. This effect can be produced in chains by the introduction of residual stresses as a result of calibration of the links. To confirm the effect axial loading fatigue tests were carried out on the chain material (7mm lifting).

There are not any standards in the design of pull and push fatigue specimens, hence they had to be designed to avoid such effects as: stress concentration and fretting. The largest possible cross-sectional areas were chosen at the centre and both ends of the specimens to avoid high stress concentration zones as well as making use of the existing specimen holder. The details of the fatigue specimen are given in Fig. 3.28.

The as-received material (bent bars) was first cut to size and straightened up before machining the centre part. The specimens were then hardened at 925° C in air for about 11 minutes and water quenched vertically to minimize the amount of distortion. They were

finally tempered at 345° C for 6 hours in air circulating furnace
(identical heat treatment as for 7 mm lifting chain), before machining
was finished off. At the centre of the specimens the distortion
varied from 0.25 to 0.43 mm (off centre line).

Three dimensional finite element elastic stress analysis of the 7 mm
lifting chain was carried out to obtain stresses at the inside
transition under 2 and 16 kN (working load limit) loads (fatigue
testing load limit). The stresses are 121 and 971 MPa with 546 MPa as
the mean stress. To achieve the same nominal stresses in the fatigue
specimens, the loads must be 2.38 and 19.07 kN (as lower and upper
limits) with amplitude of a = 8.35 kN. Four specimens were tested at
five different mean stress levels and the results are given in Table
3.6. It can be seen that the reduction in mean stress (tensile) and
increase in compressive mean stress improve the fatigue lives of the
specimens significantly. It is certainly consistent with the fact
that calibration of chains, introduces compressive residual stresses
at the surface of chains acting as mean stress, improves the fatigue
properties.

All the specimens were polished prior to any heat treatment giving a
much smoother surface finish similar to that of 7 mm lifting chains.
On the other hand, the as-machined specimens similarly heat treated
had very rough surface finish resulting in shorter fatigue lives.
This was confirmed both by Talysurf investigation of the specimen
surfaces and fatigue testing of the as-machined specimens, Table 3.7.

CHAPTER 4

RESIDUAL STRESS MEASUREMENT USING X-RAY

AND NEUTRON DIFFRACTION METHODS

4.1 INTRODUCTION

X-ray methods of measuring residual stress in crystalline materials have been tested and compared to other methods, and are in use throughout the world. Manuals have been written for their use in the United States and Japan [88,89], quoted in [90].

Usually the measurements are made manually on a conventional powder x-ray diffractometer or with a special ,unit. But there are other units that can make measurements in seconds (in the field) with reasonable precision. Both methods of measurement will be discussed later in this chapter.

The basis of the technique is straight forward and was first used. by Aborn at the U.S. Steel Co. [91], quoted in [90]. When a polycrystalline piece of metal is deformed elastically in such a manner that the strain is uniform over relatively large distance, the lattice plane spacing in the constituent grains change from their stress-free value to some new value corresponding to the magnitude of the applied stress. This uniform macrostress causes a shift of the diffraction lines to new 2θ position. On the other hand, if the metal is deformed plastically, the lattice planes usually become distorted in such a way that the spacing of any particular (hkl) set varies from one grain to another and within each grain. This uniform microstrain causes a broadening of the corresponding diffraction line. Actually, both kinds of strain are usually superimposed in plastically deformed metals, and diffraction lines are both shifted and broadened, because not only do the plane spacings vary from grain to grain but their mean value differs from that of the undeformed metal.

From the line shift due to uniform strain, the strain may be calculated and, knowing the strain, we can determine the stresses present, either by using the mechanically measured elastic constants of the material, or by a calibration procedure involving measurement of the strain produced by known stress. X-ray diffraction can therefore be used as a method of "stress" measurement [90,92,93,94,95].

The fact that x-rays penetrate only a shallow depth is in fact useful, because in many cases there are steep gradients in the macrostress near the surface. By using neutrons, which can penetrate 2 - 3 cm of steel, the macrostresses are averaged over the volume from which the reflection is obtained (usually 2 X 2 X 2 mm). The stresses can be measured within the specimen volume by using appropriate slits. . The resolution in this case is the order of 1 - 2 mm, depending on the neutron intensity. This method of residual stress measurement will be discussed at the end of this chapter.

In this chapter an attempt to measure residual stresses in 19 mm mining and 7 mm lifting chains, using a laboratory diffractometer is described. They were then measured in the British Steel Laboratories using the Rigaku Strainflex equipment. Finally, the internal residual stresses at the centre of the 19 mm mining chain were measured at the Institut Laue-Langevin, Grenoble by neutron diffraction.

4.2 X-RAY DIFFRACTION (CAMERA METHOD)

This method of residual stress measurement is carried out using a back-reflection camera with the basic principle of x-ray diffraction. The method and the experimental procedure is given below.

4.2.1 BACK-REFLECTION METHOD

X-rays from the tube are collimated to pass through a cassette containing a film, and are reflected back from the specimen, mounted on a specimen holder, thus exposing the film, Fig. 4.1. This is a part of laboratory x-ray diffractometer. Both the normal and inclined photographs may be registered on one film by using an opaque metal film cover which has two openings diametrically opposite. After one exposure is made, the film holder is rotated 90° in its own plane with respect to the cover and the other exposure is made.

The stress, σ_ϕ, at any angle, ϕ, can be calculated from this equation [93].

$$\sigma_\phi = E(S_i - S_n)/2D(1+\nu)\text{Sec}^2 2\theta \ \ \text{Tan}\theta \ \text{Sin}^2 \psi$$

where σ_ϕ is the normal stress parallel to the specimen surface, its line of action being in the plane containing the incident beam and the normal to the surface; ψ, the angle at which the incident beam is inclined to the normal to the surface. D is the distance of the film from the specimen. S_i and S_n are the radii of the rings with the incident beam inclined and normal respectively and are measured from the developed film. The accuracy of the method can be evaluated.

Correct specimen surface preparation is extremely important [96]. If dirt and scale are present, they may be ground off, the grinding must be followed by deep etching to remove the surface layer left in compression by the grinding. Then the surface is lightly polished

with fine emery paper, to remove the roughness caused by deep etching, and slightly re-etched. Depth of x-ray penetration is dependent on the absorption coefficient of the material for a given beam and the beam dimension on the experimental surface, which are defined by the slits and the geometry of the experiment. The effective depth of penetration may be calculated using appropriate formulae [97]. The effective depth of penetration of Cr radiation into steel for the (211) plane ($2\theta = 154^{\circ}$) is approximately 5.4E-6 m.

Diffraction angle, θ , for iron may be calculated. The lattice spacing (d) for a cubic crystal is given by [98]:

$$d = a/(h^2 + k^2 + l^2)^{1/2}$$

where a, the lattice parameter of iron is .28664 nm, giving d = .11702 nm; From Bragg's Law : $n\lambda = 2d \sin\theta$ and taking n=1, λ = .154178 nm for K_{α} radiation of copper, we find the diffraction angle $2\theta = 82.412^{\circ}$. λ = .229092 nm for K_{α} radiation of chromium, the diffraction angle $2\theta = 156.394^{\circ}$.

4.2.2 EXPERIMENTAL PROCEDURE

A set-up as in Fig. 4.2 was used to measure the residual stresses with an elaborate specimen holder (goniometer) which has three rotation axis and sliding capability. Instant Kodak film cassette or standard type film holder may be used to achieve exposures. Chromium radiation of 40 kV and 20 mA (.8 kW) was selected to carry out the experiment. The surface of the 7 mm lifting chain link was prepared as mentioned in Section 4.2.1 and mounted on the goniometer using a fluorescent disc, Fig. 4.3, for correct positioning. For a fixed

specimen to the film distance two exposures were made and the film was developed in usual manner, Fig. 4.4. The rings were very diffuse and the ring radii could not be satisfactorily measured using two different kinds of densitometer. Different size (medium and narrow) collimators were used with no significant improvement as well as longer exposure time (3 - 12 hours) and faster film. The standard x-ray film type was replaced by instant Kodak film resulting no change in quality of the rings, even with a flatter chain-link material.

The chain link was tempered at 600° C in a salt bath for one hour with another link annealed at 900° C for 3 hours and 1 hour, to sharpen up the rings. The whole process was repeated with sharper rings, but still the radii of the rings could not be measured satisfactorily.

4.3 X-RAY DIFFRACTOMETER

The diffractometer may also be used for stress measurement. The only instrumental changes necessary are the addition of a specimen holder which will allow independent rotation of the specimen about the diffractometer axis and a change in the position of the receiving slit. In this section the laboratory diffractometer, the principles of stress measurement and experimental procedure will be discussed.

4.3.1 X-RAY DIFFRACTION METHOD

Fig. 4.5 illustrates the angular relationship involved in a laboratory diffractometer. Radiation divergent from the source S is diffracted to a focus at F′ on the focussing circle and F on the diffractometer circle. The specimen is turned through an angle ψ

for the inclined position. Different slit arrangements can be used at F and F' to achieve both intensity and resolution, but a compromise can be made by placing narrow slits at some point between F and F' to obtain satisfactory results.   Choice of slits,   collimators and monochromators are thoroughly covered in the literature [90,92,99] and its discussion will be avoided here.

The stress equation can be written in terms of angular position 2θ rather than plane spacing as in back-reflection [100].

$$\sigma_\phi = E \; Cot \; \theta \; (2\theta_n - 2\theta_i)/2(1 + \nu)Sin^2\psi$$

where $2\theta_n$ is the observed value of the diffraction angle in the . "normal" measurement ($\psi=0$) and $2\theta_i$ its value at the inclined measurement ($\psi=\psi$). The quantity measured in the diffractometer method is $\Delta2\theta$, ($2\theta_n$ $-2\theta_i$) which is essentially the shift in the diffraction line due to stress as the angle ψ is changed.

4.3.2 EXPERIMENTAL PROCEDURE

The x-ray diffractometer with its accessories to measure the residual stresses on the 7 mm lifting chain is shown in Fig. 4.6. The intensity of the diffracted x-rays can be either plotted or printed out for a given scanning step.

Prior to the residual stress measurement, the diffractometer alignment had to be checked using a standard silicon sample (Fig. 4.3). The intensity, counts per second (cps) was plotted, Fig. 4.7, giving the

peak position (2θ) at 56.09° (compared with 56.12° expected

for the standard).

The commercially heat-treated and calibrated link was mounted on

specially made holders which were then placed in the chamber to carry

out the measurement at $\psi = 0^{\circ}$ and $\pm 45^{\circ}$. For a given scan,

the intensity was first plotted to locate roughly the peak diffraction

angle, Fig. 4.8, then the scanning step $(.01^{\circ}; .02^{\circ}$

$,.05^{\circ}...)$ was refined at the region of peak position to determine

the peak diffraction angle accurately by plotting the intensity

printed out, Fig. 4.9. The diffraction peak was not shifted equally

on either side ($\pm$ 45) to the normal direction, Fig. 4.9. To find

the minimum scanning time needed to define the peaks, intensity versus

diffraction angle plots were produced at scanning times of 1/4, 1/2,

1, 2, 3 and 4 minutes, Fig. 4.10. Shorter scanning times seem to

have produced fluctuating patterns and therefore scanning time of 2

minutes was chosen.

Two 7 mm lifting chains were tempered at 600° C for 3 and 2 hours

in salt bath. The normal calibration load was reduced by a factor

equal to the fractional reduction in hardness caused by the additional

tempering (original hardness: 345 HV30; hardness after additional

tempering: 263 HV30; normal calibration load: 38.5 kN; reduced

calibration load 23.28 kN). Three positions on the surface of each

link were considered, centre of the non-welded leg and 5 mm at either

side of it (to left and right). The diffraction angle at these

locations at $\phi = 0^{\circ}$ and $\pm 45^{\circ}$ were measured and tabulated,

Table 4.1. The links were electro-polished instead of grinding the

surface preparation process suggested by some workers. A solution of

94 % acetic acid and 6 % of perchloric acid was used with a D.C.

supply for 30 seconds.

The residual stresses corresponding to the Table 4.1 readings are given in Table4.2 and were calculated as below:

$$\sigma_\phi = -[E\cot\theta_o . \pi/2(1+\nu).180].(\Delta2\theta/\Delta\sin^2\psi)$$

where, E= 207 GPa, ν =.29 , 2θ = 136.95^o at ψ = 0° and θ_o is the diffraction angle for stress free material (usally replaced by θ).

$$\sigma_\phi = -6.2E7 . \Delta2\theta/\Delta\sin^2\psi \qquad (\Delta2\theta \text{ in degrees})$$

The stresses in Table 4.2 are not consistent (the specimen rotates 45° to the right and left) and large residual stresses exist at the noncalibrated state which had very little or no residual stresses. The errors could not be caused by the misalignment of the diffractometer, which was checked earlier. Generally the diffraction peaks are fairly broad (Fig. 4.9) specially when the specimen was rotated and the shift in diffraction peak could not be satisfactorily measured from the plot. However, all the measured stresses are compressive at the centre of the 7 mm lifting chain under various conditions.

Other measurements on other positions (such as crown) on the 7 mm lifting and 19 mm mining chain links were not possible, because of the diffractometer chamber size. Measurements were then carried out on a diffractometer especially designed for residual stress determination.

4.4 FIELD DIFFRACTOMETER (STRAINFLEX)

Residual stresses are measured in various ways in real part, either in an ordinary x-ray laboratory (Section 4.2 and 4.3) to which such samples may be brought occasionally, in a factory where frequent inspection is required, or in the field, for example in oil rigs, at large construction sites, pipelines or power stations or for parts which are too large for a commercial diffractometer. There are several units available for such situations, for example PARS [90] and Strainflex (Rigaku) which was used to carry out residual measurements on the 7 mm lifting and 19 mm mining chain links. The Strainflex equipment and results of measurements are given in this section.

4.4.1 STRAINFLEX (RIGAKU)

It consists of a goniometer, shown in Fig. 4.11 [101,102], which carries the x-ray tube on one rack and a scintillation counter on another rack. This enables the incident angle of the x-ray beam to be varied from $\psi_o = 0^o$ to 45° (Fig. 4.12) at 5° intervals and the scanning to be undertaken over the angular range $2\theta = 170^o$ to 140°. Fig. 4.13 shows the central unit consisting of the heat exchanger, for cooling the anode of the x-ray tube, the x-ray generator for supplying 30 kV, 2 - 10 mA to the tube and the microprocessor-based control and data processing unit, which controls the functioning of the goniometer and produces a printout of some parameters used in the residual stress measurements and their values, Fig. 4.14. The diffraction peak profile can also be printed for reference. A camera attachment allows qualitative assessment of the grain size and texture of a material.

The $\sin^2\psi$, fixed ψ_o technique was used to determine the residual stresses. When a material is isotropic, then a linear relationship is obtained between the diffraction peak position, 2θ , and $\sin^2\psi$ for, say, four ψ - angles (ψ_o= 0°, 15°, 30°, and 45°). The gradient of the linear regression equation is substituted into the stress equation with elastic constants of the material and $\cot\theta$ at 30° to give the residual stress.

The use of an approximately parallel beam allows tolerances of ±2 mm on the specimen position. This is achieved using transmission and receiving Soller slits to give parallel beam geometry in order to simplify the alignment procedure. Irradiated area can be varied from 20 X 5, 10 X 5 to 5 X 5 mm by restricting the Soller slits (to give parallel beam) aperture and a minimum area of 2 X 2 mm can be obtained by suitable masking of the material surface.

The diffraction peak position can be offset from its true position by the effect of 'coarse grained' and textured material [101]. The residual stress can vary between grains, and large grains favourably oriented to diffract the incident x-ray beam can contribute most to the diffraction profile leading to an erroneous peak position. Scans with different adjustments can give different residual stress values because the contributions to the diffraction peaks may come from different grains. The accuracy of the measurement made on coarse grained materials can be improved by oscillating the incident x-ray beam to allow more grains to contribute to the diffraction profile. This facility is available on the Strainflex with selection of ±3, ±5 or ±7 degrees.

'Texture' present in a material can cause a shift from the true diffraction position because the number of grains contributing to diffraction varies with 2θ whereas for an isotropic material the number remains constant. Therefore, a higher concentration of grains can give diffracted beam of higher intensity than the grains more favourably oriented for diffraction. In order to overcome the problem, the Strainflex incorporates the fixed ψ technique. This differs from the fixed ψ_o technique in which the incident x-ray beam angle is kept constant, in that the angle subtended by the surface normal and normal to reflecting planes is maintained constant during the scan. This means that the x-ray tube and counter are moved simultanously. Although this does not eliminate entirely the effects of texture, it makes a significant improvement to the analysis on textured material.

The x-ray technique is very sensitive to any surface preparation given to a material because the x-rays only penetrate into the surface approximately 10 μm. The electropolishing technique which is a stress-free process can be used to prepare the surfce and remove any undesirable stresses introduced by abrasive preparation. A solution of 14 % water, 45 % H_3PO_4 and 41 % H_2SO_4 was used with 15 V D.C. and .5 – 1.5 A, in order to electropolish the region to be examined [103].

4.4.2 EXPERIMENTAL PROCEDURE

The measurement of residual stresses on chains were carried out in two parts using the Strainflex:

a) 7 mm Lifting chain – a set of 7 mm lifting chain links calibrated

at various levels (equivalent to 30, 38.5 and 50 kN) and a noncalibrated link were prepared for the measurements. The links were all tempered at 600° C (to sharpen diffraction peaks) in a salt bath (to avoid surface oxidation) for one hour and air cooled prior to calibration. The positions (Fig. 4.15) at which the measurements are to be taken were electropolished and an area of 2 X 2 mm was masked off. The chromium tube with 1° divergence and receiving slits was used to radiate (211) planes. The stresses are given in Table 4.3 and were calculated using elastic constants of E = 207 GPa and ν=.29. The residual stresses at the outside of the 7 mm lifting chain are all compressive with the highest magnitude occurring at the crown. The residual stresses at the centre and crown increase with increase in calibration load. Certainly this can be seen from the results, but the final calibration load did not have the expected effect on the level of residual stresses.

A typical analyser output is given in Fig. 4.14 with appropriate parameters illustrated in Fig. 4.16.

b) 19 mm Mining chain - a set of 19 mm mining chain links was hardened at 970° C in salt bath for 10 minutes and water quenched and tempered at 600° C for one hour in a salt bath and water quenched/air cooled. The links were calibrated at various levels. In all measurements, an area of 5 X 5 mm at the required positions was masked off. The chromium tube with 1° divergence and receiving slits was used to radiate (211) planes (also in case (a)).

A light electropolish was carried out for the water quenched link on positions P1 and P5 to assess whether surface scale was present, although all the heat treatment was carried out in salt bath. It was

established, however, that there was no need for surface electropolish which did not have very significant effect on the measurements, Table 4.4

The residual stresses are given in Table 4.4 for water quenched links and Table 4.5 for the air cooled link, in which the measurements were made after consequent calibration. For the former case, they are all compressive and increase in calibration load did not have the expected effect on the residual stresses (at the centre and crown) which were initially quite high. This may imply that the links underwent a substantial amount of deformation as a result of water quenching, which consequently produced the compressive residual stresses. In the latter case (Table 4.5) calibration can be seen to introduce residual compressive stresses although the expected increase in these stresses on going from a calibration load of 260 to 320 kN is not observed at the crown.

4.5 NEUTRON DIFFRACTION

The x-ray method of residual stress measurement is nondestructive and can only be used for surface stresses. The hole drilling technique [30] and Sachs boring method [104] are both destructive but measure the stresses in the bulk of components. Recently a neutron diffraction procedure [90,105,106,107] has been developed which allows through-thickness residual stresses to be measured without the need for destroying the component. It does, however, require the sample to be transported to a high flux neutron source.

In this section, the neutron diffraction method will be briefly introduced and the results of the work carried out at the Institute

Laue-Langevin (ILL), Grenoble, France will be presented.

4.5.1 NEUTRON DIFFRACTION METHOD

Neutron diffraction and x-ray methods both measure components of strain directly from changes in the lattice spacings of the crystals. Residual stresses are then calculated from these strains. Neutrons can penetrate several centimeters into most materials so that bulk strains can be investigated.

The principles of the neutron diffraction technique are illustrated in Fig. 4.17. If d is the lattice spacing in the direction of $\underline{Q}$ and 2θ is the scattering angle, then the lattice strain ε, in the direction of the scattering vector is given explicitly as [106]:.

$$\varepsilon = \Delta d/d = -\Delta\theta \; Cot\theta$$

To obtain the absolute strain the lattice spacing of the unstrained material d_o must be known.

The sensitivity of the method depends upon the angular resolution of the systems and upon the volume of material sampled. The sensitivity of the method may be improved by using multi-slit Soller collimators to produce parallel beam with minimum loss in intensity. The volume of the material sampled is defined by the incoming beam and may be limited by inserting a mask just in front of the sample as illustrated in Fig. 4.17.

A large volume will permit a rapid counting rate and speed recording, but will give average strains over the volume which may not be

satisfactory in the region of steeply changing residual stress. A compromise is therefore required by choosing a few cubic millimeters.

A Bragg reflection, from a region of constant strain, usually has a Gaussian intensity profile, the centre of which may be determined accurately by a peak fitting routine, Fig. 4.18.

4.5.2 EXPERIMENTAL PROCEDURE

The 19 mm mining chain link (calibrated at 350 kN) which was used in Section 4.4, was chosen to undertake the task of residual stress measurement, Fig. 4.19. The measurements were carried out using the high resolution powder diffractometer situated on a thermal neutron guide from the High Flux Beam Reactor at the ILL.

Measurements were made of (211) peak shifts and profile changes as a function of position and orientation in the chain link. The (211) reflection was chosen because it was expected that the (211) strains would be similar to the average engineering strains and, using a neutron wavelength of 0.19106 nm, the angle 2θ was close to 90° thus giving optimum spatial resolution. In the x and z directions a sampling volume of 2X2X2 mm was used with the link mounted horizontally. Measurements in the y direction a volume of 2X2X10 mm was used with link mounted vertically. Measurements were made in a region close to the centre of the long side of the link as indicated in Fig. 4.20.

The measurements can be both plotted, Fig. 4.18, and printed Table 4.6.

4.5.3 RESULTS AND CALCULATIONS

Peak centres and widths obtained by computer fitting single Gaussians to the data, are plotted, Fig. 4.21 and 4.22. The width of a peak, from a perfect unstrained crystalline powder at the angle of the (211) steel reflection, arising solely from instrumental factors, is about 0.3°. However, it is found in most experiments on engineering steels that have been annealed and elastically strained, that peak widths are usually in the region of 0.35° to 0.45°. If the steel has been plastically strained or there are steep strain gradients additional peak broadening and sometimes changes in peak shapes occur.

In this experiment single Gaussians provide a satisfactory fit to all the peak profiles but the measured peak widths are mostly in the range $0.7^{\circ} \pm 0.1^{\circ}$. This is not exceptional and would suggest that there is extensive microstrain present in the chain link. At $y = 6$ mm and 13 mm the peak widths are 1.26° and 0.88° respectively for the z direction data but remain near 0.7° for the x and y data. The measuring positions at which the z peaks are extra wide do, however, coincide with regions of very steep z strain and their extra widths, and decreased peak heights, are quantitatively as would be expected for the strain gradient observed and the size of sampling volume used.

Fig. 4.23 shows the strains and Fig. 4.24 the stresses calculated from the peak centre positions assuming x, y and z directions correspond to the principal stress directions. As no measurement of diffraction angle was taken on a stress-free material, it was found from the stressed state of the chain link. The diffraction angle

corresponding to equal lattice spacing in all three directions was obtained from the plots of lattice spacings in the x and y-directions versus z-direction, Fig. 4.25 (Table 4.7). Experience and balancing considerations would suggest that this point corresponds to position of minimum strain and stress, and hence it was used as the strain free zero for calculation purposes. From Bragg's Law, considering $\lambda =$ .19106 nm and d = .11723 nm, the diffraction angle is calculated $2\theta_o = 109.154^o$. Having ($\Delta\theta = 2\theta - 2\theta_o$), the strains can be calculated from the following expression and given in Table 4.8, 4.9 and 4.10.

$$\varepsilon = -6.207E-3 \; \Delta\theta \; (\Delta\theta \text{ in degrees})$$

From these strains, stresses were calculated and are shown in Table 4.8 and 4.9.

The x and y strains are small and opposite in sign in comparison with the large z strains suggesting that they substantially arise as a Poisson's ratio effect. The corresponding x and y stresses are at all positions small, whereas the z stresses change rapidly from compression to tension and back to compression as a function of position y. There were very large strains observed around y = 5 mm.

All three stresses are plotted along the positions with the absolute maximum principal stresses from the finite element analysis (Table 4.11) Fig. 4.26. There is a good agreement between the neutron diffraction and finite element results. Stresses in the x and y-direction are very close and have opposite sign to σ_z. All stresses meet at zero stress position.

The errors from all the measurements were also determined ranging from ±19 to ±64 MPa. The largest errors occurred at the steepest stress gradient implying that the irradiated volume is too large and better results may be obtained by smaller volumes with further refinements. It is anticipated that the residual stresses can be measured by this technique to an accuracy of about 20 MPa. Furthermore, the accuracy may be possibly improved by a factor of 2 due to better statistics (better curve fitting techniques) at substantially reduced counting times [106].

CHAPTER 5

RESIDUAL STRESS MEASUREMENT USING STRAIN

GAUGE METHOD

5.1 INTRODUCTION

The strain gauge method of stress measurement is the most widely used technique in industry today. It involves the fixing of one or more strain gauges (length of wire or foil of known resistance and suitable form cemented to a non-conductive backing) to the surface of the material whose strain is to be determined. It is essential that intimate contact between the material and the gauge is assured. The gauge will then faithfully record the true surface strain. Surface preparation is probably the most vital factor effecting the adhesion of the gauge to the surface, and special cleaning technique must be adopted.

Assuming that the gauge is correctly bonded to the surface, any strain in the material is then transmitted directly to the gauges, which therefore increases or decreases in length and cross-sectional area. These changes in dimension are accompanied by a change of resistance which can be related directly to strain by multiplying by a constant known as gauge factor. This is provided by the manufacturer and for most conventional gauges is of order of 2 to 2.2. In most strain gauge measurement instruments or bridges this step is done automatically and the strain is read directly from a dial. Strain gauges thus represent a relatively simple method of obtaining a surface strain values.

There are a number of specially developed gauges. These are self-adhesive, high sensivity semi-conductor, fatigue gauges and etc. [108,109,110,111,112,113,114].

There are hundreds of strain gauge types available, it is therefore

important that the potential strain gauge users be aware of the various factors which might influence their decision on the choice of a gauge for his particular application.

The advantages of strain gauges as an experimental stress analysis technique can be summarised as follows:

relatively simple and quick.
direct reading.
many different type of gauges to suit particularly every condition.
used particularly in any environment.
no component size limitation.
good accuracy.
repeatable technique.
applicable to static, dynamic and transient.
used in actual service condition.
reduced weight and size compared with convensional mechanical transducers.
temperature effect mostly eliminated.
remote reading possible.
sensitivity can be improved using various wire.
finally, excellent repeatability.

The Bauschinger effect - the change in the stress-strain curve of a metal following plastic deformation in the appropriate direction - is of interest in connection with residual stress determination using the strain gauge technique.

The determination of residual stresses in the surface of 19 mm mining chain using the strain gauge technique is discussed with reference to Bauschinger effect in the next section. Apart from the standard 19 mm mining chain link, elliptical and eight shape links were formed, Section 5.3, and will be considered in the stress measurement process with the 22 mm oval cross-sectional mining chain. The heat treatment and surface preparation for the strain gauge work, on the chain links and test specimens to determine material stress-strain curve are presented is Section 5.4. The strain gauge selection and mounting processes are given in the following sections. Finally, the experimental procedure and results with calculation of the total and

residual stresses are given in Sections 5.6 and 5.7 respectively.

5.2 PRINCIPLE OF RESIDUAL STRESS DETERMINATION AND BAUSCHINGER EFFECT

Let us assume that the strain is followed at a particular position on a chain link, where the strain is uniaxial. When the chain material is loaded over its yield point (B), on BC in the stress-strain diagram, Fig. 5.1, on unloading, various possibilities arise. Thus the material behaviour may be such that:

a) residual tensile stress is achieved, point D.

b) residual compressive stress is achieved, point F.

c) no residual stress is achieved, point E. If, by any means the strains at points C and D or E or F could be measured, the corresponding residual stress could be determined. Strain gauges were here used for this purpose.

If the material at the unloaded condition (E), is loaded in compression, it yields at σ_y, and follows EFG rather than EF'G' in tension ($\sigma_{y'} < \sigma_y$). This phenomenon was first reported by Bauschinger in 1881 and carries his name, i.e. Bauschinger effect [115,116,117]. One way of describing the amount of Bauschinger effect is by the Bauschinger strain (β). This is the difference in strain between tension and compression curves at a given stress. As shown in in Fig. 5.1 permanent softening may be measured when parallelism is attained between forward and reverse flow curves, and is function of forward strain (ε_c) [118]. The Bauschinger effect was not considered in the finite element determination of the residual stresses, hence the stress values ($\sigma_{F'}$) will be higher than the measured values (σ_F). Bauschinger charts can be evaluated and plotted from a limited number of tests using a computerised method for

the determination of the intensity of the Bauschinger effect of the metallic materials [119].

5.3 FORMING OF EIGHT SHAPE AND ELLIPTICAL CHAIN LINKS

The dimensions of the eight shape and elliptical chain links were worked out for $\theta = \pm 24^{\circ}$ (Fig. 5.2 a) with the same pitch and nominal diameter as the standard 19 mm mining chain link. To achieve the required geometries the standard link had to be either pinched or pushed out by 7.4 mm (3.7 mm each side) at the barrel centre. The as-received standard links were first had to be annealed at 600° C to ease the forming of the links. Fig. 5.3 (a,b,c and d) illustrates the forming processes used for eight shape and elliptical chain links.The rollers, pins and the punch had to be hardened after machining to prevent bedding in. In both cases a 60 tonne press was used applying about 5 and 25 tonnes of load to form the elliptical and eight shape links respectively. The finished links are given in Fig. 5.2 b with the 22 mm oval cross-sectional mining chain link shown at the bottom.

5.4 HEAT TREATMENT OF CHAIN LINKS AND PREPARATION OF MATERIAL TEST SPECIMENS

Three kinds of heat treatment were carried out on the chain links to correspond to the x-ray work (air cooled/water quenched after tempering) and the finite element work on the as-received condition:

a) Hardened at 970° C in a salt bath to avoid surface decarburization for 15 minutes and water quenched; tempered at 600° C (in the x-ray work to sharpen the peaks) in salt bath for one hour and water quenched (material 1).

b) As in (a) except air cooled after tempering (material 2).

c) As in (a) except the tempering temperature and time were
475° C and 4.5 hours (air cooled) respectively (manufacturer's
heat treatment), (material 3).

The surfaces of the different links were polished prior to the marking
off the strain gauges positions accurately using the divider head with
appropriate packing plates machined for this purpose, Fig. 5.4.

Tensile test specimens, Fig 5.5, were machined from the legs of the
chain link to obtain the stress–strain curves of the material
corresponding to the above heat treatment conditions. The threaded
ends were used in tensile and squared parallel ends in compression
conditions. The specimens diameter for material 1 was 7.31 mm and
material 2 and 3 was 7.92 mm.

5.5 STRAIN GAUGE SELECTION AND MOUNTING

A brief account of steps in selection of strain gauges out of a very
large number of gauges will be given in this section with some
cautions on the mounting procedure.

5.5.1 STRAIN GAUGE SELECTION

The initial step in preparing for any strain gauge installation is the
selection of the appropriate gauges for the task. Careful, rational
selection of gauge characteristics and parameters can be very
important; optimizing the gauge performance for specified
environmental and operating conditions, obtaining accurate and
reliable strain measurements, contributing to the case of

installation.

The installation and operating characteristics of a strain gauge are affected by the following parameters, which are selectable in varying degree [109]:

strain-sensitive alloy
backing material
gauge length
gauge pattern
self-temperature compensation
grid resistance

There are some operating constraints which are generally expressed in the form of requirements such as :

accuracy
test duration
stability
cyclic endurance
maximum elongation
simplicity and ease of installation

Since the gauge was required to remain on the link as the link was plastically deformed, a "post-yield" gauge was selected. A "YF" post-yield gauge, consists of Cu - Ni foil with plastic backing, operating temperature - 20° to + 70° C with 10 - 20 % strain , supplied by TML [109], was chosen. The YF gauge has a gauge length of 2 mm , with 1.8 mm gauge width (the smallest available) and 7.4 X 4 mm base. Since the strain gauges tend to average the strain over the area covered by the grid and the average of any non-uniform strain distribution is always less than the maximum, a strain gauge which is noticeably larger than the maximum strain region will indicate a strain magnitude which is too low, hence 2 mm gauge was chosen to avoid or at least minimize this effect. Single grid strain gauges are sufficient for the measurement, because only the stresses in the longitudinal direction of the chain link were to be measured. There was no option to choose a gauge with 120 Ω (± .3) rather than higher resistance in reducing heat generation rate and decreasing lead

wire effect. The gauge factor is 2.11 for the YF strain gauges which are supplied in packs of 10. The CN strain gauge adhesive recommended by the TML for YF type gauges was chosen. The adhesive has the same operating temperature as the YF gauges.

5.5.2 STRAIN GAUGE MOUNTING

TML connecting terminals were chosen to provide convenient junction points to connect gauges to instrumentation leads. They are made up of .033 mm thick copper foil and an insulation laminated with glass-epoxy approximately .15 mm thick with operating temperature up to 180° C.

The following steps were taken in mounting the strain gauges: . .
a)
Surface preparation of specimens – an area of approximately 2 – 4 times of base length in diameter was ground using an abrasive paper, so as to remove irregularity, rust and coating. Centre line to the gauge position was marked off without the line crossing the area on which the sensing element is directly placed. Some solvent such as methanol was used to clean the surface.
b)
Bonding to metal – a small drop of CN adhesive was used on the reverse side of the strain gauge and the gauge was plastered on the prepared surface of the specimen. The plastered gauge was set at its proper position and then instantly covered with a polyethylene sheet and was vertically pressed with thumb fairly hard for over a minute and it was then possible to take measurements after 15 minutes. When the adhesive set, the polyethylene sheet was peeled off clearly. Similarly, the connecting terminals were bonded at convenient

positions.

c)

Coating and soldering - the gauges and lead wires were soldered to the terminals. The lead wires were then anchored to the specimens and links, to avoid damages occuring from pulling before and during the test, and can be seen in Fig. 5.6 and 5.7 (a and b). Also, the gauges were coated with silicon rubber for protection. The equipment used in mounting the strain gauges are shown in Fig. 5.8. Finally, the whole installation was checked for damage and malfunctioning.

5.6 EXPERIMENTAL PROCEDURE

Material test specimens and chain links were tested on different testing machines and the procedure for each case is given separately below:

a)

Material test specimens - these specimens were tested using a 100 kN Instron testing machine, Fig 5.7 (a and b) and the strain gauge data logger with its peripherals shown in Fig. 5.9. The strain gauges were first soldered into the connection box before setting up the data logger and energizing the strain gauges (1 volt). To obtain the material stress-strain curve, the specimens were loaded up to the required strain in tension before unloading takes place, scanning at various load levels, Fig. 5.7a. The specimens were then loaded in compression and unloaded to zero just before buckling (two strain gauges start to disagree by large amount) using the compression bed, Fig. 5.7 b. A typical load- extension curve of a specimen depicting the loading-unloading cycle in tension and compression is given in Fig. 5.10 (extension here measured by cross-head displacement).

b)

The chain links corresponding to the x-ray works were calibrated using the 40 tonnes Amsler testing machine with two partially surface ground chain link holders, Fig. 5.11, whereas , the second set of chain links (different geometries) were calibrated using a Losenhausen testing machine with 22 mm diameter holders. After soldering the lead wires to the connection box and energizing the strain gauges, the links were loaded and unloaded (up to 100 KN) a few times in steps of 20 kN to check the response of the strain gauges. Each link was loaded up to the required calibration load in steps of 20 kN, scanning at each step before unloading in similar manner. The scanning outputs were printed for all 12 strain gauges, numbered as in Fig. 5.12, from which the loaded and unloaded strains corresponding to the calibration load could be read.

5.7 RESULTS AND CALCULATION OF RESIDUAL STRESSES

The material test specimen results are given in this section with results and calculation of residual stresses obtained by the x-ray and the finite element method.

5.7.1 STRESS-STRAIN CURVE OF CHAIN MATERIAL

The stress-strain curves of all three different chain materials are plotted from the material test specimen results, Fig. 5.13, 5.14, and 5.15. The material properties of these materials can be read and were determined from these curves:

	σ_y(MPa)	ε_y(µε)	Hardening parameter,H'
1)	890	4260	963
2)	890	4250	646
3)	1000	4780	531

Young modulus was found to be 209 GPa. The work hardening parameter
is defined as the slope of plastic part of the material stress-strain
curve.

A four link 19 mm mining chain of material 2 was pulled using the
Amsler testing machine. The ultimate failure load was 348 kN (364 kN
for single link), hence nominal stress is 614 MPa. The overall
extension was 14.6 % (gauge length was 336 mm and elongation of 49
mm), and the test speed was 3.77 mm/min. (test period was 13
minutes).

5.7.2 RESULTS AND RESIDUAL STRESS CALCULATION RELATING TO THE X-RAY WORK

The strain readings from gauges in equivalent positions were found to
be very similar, but the readings from non-equivalent positions were
markedly different, Fig. 5.16 to Fig. 5.21 (gauge positions shown in
Fig. 5.12). The gauges at 60° to the crown in most of the cases
showed an unexpected increase in the strain while the link was
unloaded, Fig 5.17. This kind of behaviour was reproduced at these
positions using the finite element method, Chapter 8.

The extreme strains - when fully loaded at the calibration load and
those in the unloaded condition, are tabulated from figures similar to
Fig. 5.16, Table 5.1 and 5.2 for the links made up of material 1 and
2 respectively (two links of each). The residual stresses were then
evaluated as described in Section 5.2, Table 5.3 and 5.4. The total
stresses were also determined at the calibration levels, Tables 5.5
and 5.6. The average total and residual stresses for each case

(material 1 and 2) at various calibration levels are plotted, Fig. 5.22 and 5.23 at the outside surface of the 19 mm mining chain. It can be seen from the Fig. 5.22 that the links yielded at the crown and barrel at all calibration levels. An increase in the calibration load levels did not have any significant effect on the total stress levels at the yielded regions (crown and centre) neither did the material type as such, Fig. 5.22 and Table 5.7. The residual stresses, on the whole, are compressive at the outside and inside surface, and increase in calibration load increases the magnitude of the residual stresses in both cases, not so much at the inside as the outside, Fig. 5.23 and Table 5.7. The results obtained for material 2 calibrated at 350 kN are not reliable because of the fact that the calibration load was not achieved properly (being very close to the failure and unable to control).

Residual stresses obtained from the x-ray work (Chapter 4) for both the 19 mm mining and 7 mm lifting chains are given in Fig. 5.24 with the corresponding strain gauge work. The patterns of stresses are similar but big variation in magnitude exist at the centre of the 19 mm mining chain for material 1. On the other hand, the agreement between the two sets of stresses at the crown is good for both materials but not at the barrel, Fig. 5.25.

5.7.3 RESULTS AND RESIDUAL STRESS CALCULATIONS OF DIFFERENT LINK GEOMETRIES

Two samples of each geometry, standard, eight shape, elliptical and oval cross-sectional links with the installed gauges at appropriate positions were calibrated at three different load levels using the Losenhausen testing machine and the strains at the extreme load

(calibration load and unloaded) levels are tabulated, Tables 5.8 to 5.11. The residual stresses and total stresses for all the calibration loads were determined using the principle outlined in Section 5.2, Tables 5.12 to 5.19.

Total stresses in mining chains from the strain gauge work were compared to those determined by the finite element method (Chapter 8), under load before and after onset of plastic flow in the links, Fig. 5.26 and 5.27. The stresses are in good agreement indicating the validity of both methods.

The effect of link geometry on the total and residual stresses (average of two links) can be seen in Fig. 5.28 and 5.29 for the first calibration load, and effect of calibration load on the residual stresses for various link geometries are given in Fig. 5.30 to 5.33. The elliptical and oval cross-sectional links follow very similar pattern, (Fig. 5.32 and 5.33), the residual stresses becoming tensile at the outside transition, Fig. 5.29. The eight shape and straight side links behave similarly (Fig. 5.30 and 5.31),eight shape link starting with tensile at the centre,with a wider gap at the centre moving to the crown as the calibration load rises, resulting in larger stresses (in magnitude) for both links, Fig. 5.29. The residual stresses at the inside centre and transition are, on the whole compressive and increase (in magnitude) as the calibration load increase, Table 5.20. At the centre of the eight shape link (inside) there is very little residual stress whereas at the transition very high compressive residual stress exists, Fig. 5.31.

Once, the surface of the links has yielded, there is very little increase in the total stress, Tables 5.20 and Fig. 5.28, except for

the eight shape link, Table 5.17. Hence, as the calibration loads
increase the yielding extends to the interior from the surfaces
leaving the surface stresses unchanged. The total stresses for
various link geometries are given in Fig. 5.28 at the first
calibration load with no variation at the crown. It can be seen that
the stress near the crown depends little on link shape.

On the whole, increase in calibration load increases the total and
residual stresses significantly in all geometries at the outside
surface and inside transition and centre regions.

CHAPTER 6

FINITE ELEMENT BEAM ANALYSIS OF CHAINS (1–D)

6.1 INTRODUCTION

Under fatigue conditions, the varying stress caused by the external loading is added to any existing residual stresses: the position and magnitude of the resulting stress is important in determining the fatigue life.There are various ways of calculating these stresses numerically,such as: finite element beam analysis,two and three dimensional stress analyses. The finite element beam analysis of chains is extremely cost-effective in evaluating a multitude of different link geometric configurations. The more costly two dimensional contact and three dimensional solid stress analysis will be the theme of the following chapters.

The selection of beam elements suitable for large rotations,small strain applications is of considerable interest, and many possible formulations exist. In some problems,warping of the cross-section is important; this is specially true for some open sections. Sometimes distortion of cross-section in the plane must be considered;the classical example of this is the pipe bend. There have been attempts to provide a library of elements broad enough to satisfy most needs for beam type modelling.

In the ABAQUS library,beams in plane and beams in space are included. Since in chains only planar deformation occurs, due to geometry and loading,it is wise to use plane beam elements. Beams (Timoshenko beam element) that allow transverse shear are considered here. In these beams (element B22), additional approximation (to that of classical Euler-Bernoulli) is invoked in that the response to this shear is purely elastic: thus only axial, bending and torsional strains are considered in the nonlinear constitutive modelling. It is also

assumed that the cross-section does not deform in its section; the transverse shear is not considered to produce warping in the section: rather it is treated as a small relative rotation between the normal to the plane of the cross-section and the beam axis. The basic formulation of these elements is given in [39,120].

Work carried out by the SDRC describes the study of design modifications to a (9/16") 14 mm nominal diameter wheel chain link [43]. The effect of link geometry (shaved,oval cross-section, eight shape,standard) given in Fig. 1.3 and 5.2a, on the position of highest elastic stresses at the shoulder has been mainly investigated. An elastic beam element with point load at the crown was used and it was concluded that :

1. The standard link configuration is the optimum geometry to minimize the inner surface tensile streses at the shoulder.

2. The shaved design does not appear to offer a significant advantage over the standard design.

3. The eight shape design results in higher stresses at the shoulder and lower at the leg.

4. The oval cross-section design provides a desirable means to reduce the shoulder stress without dramatically increasing the stress levels at the leg.

The purpose of this phase of the analysis is to evaluate the merits of two possible design modifications of alloy steel mining chain and compare them with the standard design configuration for such links in the light of the SDRC work. The basis for this is the 19 mm nominal diameter link design with semi-circular ends and the straight legs (standard). The general conceptual geometry for the two modified links is illustrated and given in Chapter 5.

The following is a description of the modified link geometries analysed,Chapter 4.

1. The wire cross-section remains constant while the line of centroids curves inwards towards the centreline of the link,eight shape (pinched).

2. The wire cross-section remains constant while the line of centroids curves outwards from the centreline of the link, elliptical.

In this chapter, the loading assumption used in the beam analysis of chains will be discussed. Later, the 19 mm mining chain is analysed elastically and elasto-plastically to evaluate residual stress distributions at various calibration levels. The stresses will also be given through thickness of the chains at different sections. Finally, a similar analysis will be carried out for the 7 mm lifting chains.

6.2 LOADING ASSUMPTIONS

The loading of the chains can be modified in many different ways. A point load at the crown used by the SDRC is very crude and causes a convergence problem locally in the elasto-plastic analysis. Ideally, contact analysis in three dimension would give the appropriate contact area and pressure envelope at the crown. In the beam analysis a compromise was made by assuming an elliptical pressure envelope at the crown. The extent of pressure was limited to one element at the crown only and the ratio of the loads at the nodal points are calculated as below: The general parabolic distribution of loads can be solved for the particular solution [42]:

$$q = a + bx + cx^2$$

where q is the pressure at any point x (0<x<1).

$A = a + b/2 + c/3$

where A is the area under the curve which is the total load.

$Q_1 = a/6 - c/6$

$Q_2 = 2a/3 + b/3 + c/5$

$Q_3 = a/6 + b/6 + 3c/20$

where Q_1, Q_2 and Q_3 are the loads at positions $x = 0$, .5 and 1.

General Case	Special Case
Area under the curve is unity	$a + b/2 + c/3 = 1$ (1)
At $x = 0$, $dq/dx = 0$	$dq/dx = b + 2cx = 0$ (2)
Finally, $q = 0$ at $x = 1$	$a + b + c = 0$. (3)

Equation (2) $b = 0$

Equation (1) $a + c/3 = 1$ (4)

Equation (3) $a + c = 0$ $a = -c$ (5)

Substitute (5) into (4) $-c + c/3 = 1$ $c = -3/2$ and $a = 3/2$

Therefore

$$Q_1 = 11/40$$

$$Q_2 = 28/40$$

$$Q_3 = 1/40$$

Check $\Sigma Q = 11/40 + 28/40 + 1/40 = 40/40 = 1$

The ratios of the loads area 11/40, 28/40 and 1/40 from the crown.

6.3 19 mm MINING CHAIN

Beam modelling of chains is the simplest and cheapest of all the modelling and has been attempted here to obtain an understanding of the total and residual stress distributions in different geometries of

chains.   Only one quarter of the 19 mm mining chain was chosen by
making use of geometrical and loading symmetry.   The quadratic beam
element (B22) uses Timoshenko beam theory and includes shear
deformation [39,120].   The finite element mesh consists of 15 B22
elements (3 noded, quadratic interpolation) of approximately equal
lengths in all the geometries, Fig. 6.1.   The model is constrained at
the crown in the x-direction, at the centre in the y-direction and
rotation about the z-direction at both ends.   The cross- section of
the model is specified easily using the standard section in the ABAQUS
library.   The program assigns integration points on the section and
integrates the section numerically to obtain generalised force-moment/
strain-curvature relations.   This in conjunction with numerical
integration along the beam length, allows complete generality in
material response (plasticity) , since each point of each section is
individually considered by the constitutive routines.   The default
integration for the beam in a plane (B22) is 5 points and up to 9
points are permitted.

Geometrical nonlinearity was also considered with residual force and
moment tolerances of .1% and 1.% respectively.

6.3.1 ELASTIC ANALYSIS

The model described in the previous section was analysed elastically
with Young's modulus, E=205 GPa.   The whole loading was applied in one
increment and the results are presented below:

The stresses (largest absolute principal stresses) were plotted at the
inside, centre and outside for all the geometries,Fig. 6.2.   The
loading was the manufacturer's calibration load for this grade of

chains. The stresses have similar pattern for all geometries at the inside,centre and outside, except at the leg region, where the elliptical link has higher and eight shape link lower stresses than that of the standard link. The position of the largest tensile stress at the inside of chain link is different for all the geometries: in the case of elliptical link it is at the centre of the leg rather than the transition zone for the other geometries. The standard link seems to be at the middle of two extreme geometries (elliptical and eight shape). The stresses at the outer and inner fibres of all the geometries have opposite sign. There is no variation of stress at the centroid of the links due to geometry, but the stress reduces to zero at the crown from a tensile value at the centre. It passes through the intersection of internal and external stress curves.

The stresses at the crown (3 integration points) were discarded: the method of load application and the approximation of the method give unrealistically large stresses. This will also apply to all the other beam analysis results.

6.3.2 PLASTIC ANALYSIS

To determine residual stresses the elastic beam model was used witn material nonlinearity included. The elasto-plastic material model considered has the following properties: yield stress, σ_y = 1000 MPa and hardening parameter (H')=531 MPa (experimental values obtained in Chapter 5). The load increments may be applied automatically (to find the failure load) or manually (to determine residual stresses).

6.3.2.1 TOTAL STRESSES

Stresses at the calibration levels, 260,320,and 380 kN were computed for all three geometries and plotted at the inside, centre and outside the links, Fig. 6.3,6.4 and 6.5. At the yielded regions, the increase in calibration load does not have significant effect on the stresses, whereas in the elastic zones, it results in reduction of stresses for the eight shape link (Fig. 6.4 and 6.5). At all the calibration loads and for all the geometries the barrel and crown have yielded both at the inside and outside, leaving the shoulder elastic except for the eight shape link which has the central region of barrel still elastic. The elastic analysis gave some insight into the stress distribution before the elasto-plastic analysis, which is not very different.

All the geometries were tested to failure using automatic incrementation , i.e. the model was loaded up to a point, where the solution did not converge (very small load increment produces very large unrealistic displacements), hence the failure was achieved. The failure loads were 380, 380 and 324 kN for the standard, eight shape and elliptical links respectively. The load carrying capacity of the' models are lower than the tested values: 24%, 24% and 35% respectively.

Stresses may be computed through thickness of the beam models at 9 points, and are given in Fig. 6.6,6.7 and 6.8, for all geometries at calibration load, (cl)=320 kN, at important positions such as central barrel, 30 and 60 degrees to the crown. There are not appreciable differences in total stresses at the sections 30 and 60 degrees to the crown between different link geometries but at the centre the standard link stresses lie between the elliptical and eight shape link stresses.

The displacements at the centre of barrel and crown are given in Table 6.1 for all the geometries at various calibration loads. The elliptical link has moved in the most, whereas the eight shape link appears to be the stiffest. The deformed meshes at cl=320 kN are given for all the geometries, Fig. 6.9. The whole mesh seems to pivot about a point 45 degrees to the crown.

6.3.2.2 RESIDUAL STRESSES

The chain models with elasto-plastic material properties were loaded up in 30 equal increments for all calibration levels and unloaded in 10 equal increment to obtain the residual stresses. The residual stresses for all cases were plotted, Fig. 6.10,6.11 and 6.12. The stresses at the crown are invalid due to the load application there.

The residual stresses are compressive at the inside of the barrel except for the eight shape link and tensile at around the crown. Higher calibration loads results in higher compressive stresses at the barrel and lower tensile residual stresses at the crown and nearby, Fig. 6.11.

The residual stresses at the centroid of the chain links are tensile in all cases, nearing zero at the crown. The eight shape link starts with zero residual stress at the centroid in the barrel and rises to maximum at the transition zone, and finally drops to zero before rising again at the crown, Fig. 6.12. As the calibration load increases, the tensile residual stresses decrease at the barrel and some parts of the shoulder in the case of the standard and the elliptical links.

The residual stresses are compressive at the outside in all cases. The standard link seems to have larger residual stresses than the other geometries. Higher calibration loads result in higher residual stresses in all cases, Fig. 6.10.

The residual stresses through the thickness of the chain models are also given in Fig. 6.13,6.14 and 6.15 at various important sections, such as centre, 30 and 60 degrees to the crown. The stresses are virtually all the same at 60 degrees and close at 30 degrees to the crown but vary significantly at the centre, where the standard link stresses have a very similar pattern to that of the results obtained using the neutron diffraction technique (Chapter 4), Fig. 6.13.

6.4 7 mm LIFTING CHAIN

7 mm Lifting chain which was used in fatigue testing in the experimental work (Chapter 3) was analysed here using the finite element method. The same strategy as in the 19 mm mining chain was taken in the elastic and elasto-plastic analysis for total and residual stress calculations. The mesh of 15 three noded beam (B22) elements was used. The material model is the same except for the yield stress (=1148 MPa). The elastic stresses at the inside, centre and outside are given in Fig. 6.16. The stresses at the inside of the barrel are twice that of the outside and the stresses at the centroid are virtually half way between the two outer fibres. All the stress curves meet at an angle about 47 degrees to the crown, at the calibration load of 38.5 kN (the manufacturer's calibration load for this grade of chain). The stresses from the elasto-plastic analysis have a similar pattern to that of the elastic analysis except for the centroids, where the stresses have shifted up, Fig. 6.17. The

stresses again all meet at an angle about 38 degrees to the crown. Higher calibration loads cause the stresses to rise at all locations; it can be seen that the stress patterns are similar to that of the mining chains (standard link).

Residual stresses are also computed and presented in Fig. 6.18. They are compressive at the outside, inside and tensile at the centroid fading away at the crown. Higher calibration loads result in higher residual stresses, Fig. 6.18. Deformations of the model at various load levels are given in Fig. 6.19.

Total and residual stresses are given in Fig. 6.20 and 6.21 for sections at the centre, transition, 30 and 60 degrees to the crown. The residual stresses at the centre and transition are equal and the pattern is the same as the results obtained from the neutron diffraction technique. The residual stresses at two other sections are also equal (Fig. 6.21).

CHAPTER 7

FINITE ELEMENT CONTACT ANALYSIS OF CHAINS (2–D)

7.1 INTRODUCTION

In the finite element stress analysis of chains, the modelling of the applied load has paramount importance in the evaluation of total and residual stresses. This requires a full scale investigation of the contact between two links when loaded. Stress analysis of bodies in contact is an important class of structural mechanics problem. The extent of the contacting surfaces may depend on the level of applied loads, and the contact may be frictional or smooth. Such stress analysis problems are nonlinear and therefore quite complex solution methods.

A contact problem occurs when at least two of the bodies not mechanically joined touch each other without becoming rigidly attached. They can touch either at a point, along a line, over a surface or over a combination of these elements, defining a contact region. The transmission of forces from one body to another is done through this region by normal compressive stresses and by tangential or shear stresses if friction exists. While the initial state of contact is determined by the geometric features of the bodies, the extent of the contact generally changes when the bodies are deformed by the applied loads or other source of stress.

Exact solutions of contact problems exist for simple, idealised problems , requiring sophisticated mathematical analysis [121,122]. Such solutions are not feasible for contact problems involving more complicated geometries, such as chains, although an attempt was made to solve the contact between links elastically in the next section.

Chan and Tuba [123] presented an incremental procedure for frictional

and frictionless contact problems. An over-relaxation procedure was used to solve the set of nonlinear equations. The equilibrium equations are formulated for each body separately in terms of the displacements and the contact forces. Another condition is imposed, that the points in the contact bodies cannot interpenetrate. The nodal displacements can then be solved for and an iterative process carried out within the step to allow several points to come in contact. The process is repeated with higher loads to obtain new contact points until the external load is reached.

Fredriksson and Urzua et al [124,125,126] presented an incremental formulation of contact problems of frictional and frictionless contact at the same time. The equilibrium equations are formulated in terms of unknown nodal displacement increments and the interface tractions are computed from the stresses at the end of each step. These tractions are applied to the next step by computing an equivalent nodal load vector. At each step, the appropriate constraints are applied for nodes in contact. Due to finite increments, iterations are necessary within the increment. This procedure is very similar to the standard approach for elasto-plastic problems. A similar algorithm was coded up in ABAQUS (interface and gap elements) with two and three dimensional contact problems with material and geometrical nonlinearities.

The primary objective of this chapter is to evaluate the contact pressure and contact area for 19 mm mining and 7 mm lifting chains, in two dimension with no friction considered, and to investigate how the method of load application affects the total and residual stress patterns. The contact pressure and contact area between links will be investigated analytically for elastic conditions, and numerically

using interface elements for plane stress and plane strain conditions. Secondly, this may be used to model the contact pressure in three dimensional stress analysis rather than a full and costly three dimensional contact stress analysis (Chapter 8).

7.2 PRESSURE BETWEEN TWO LINKS IN CONTACT

The contact between two elastic links may be derived from the more general case of contact between two elastic bodies given by Timoshenko and Goodier [121]. The principal radii of curvature of one of the bodies are R1 and R'1, and of the other body, R2 and R'2; ψ the angle between normal planes containing the curvatures 1/R1 and 1/R2, then the constants A and B are determined from the equations

$$A + B = 1/2 \ (\ 1/R1 + 1/R'1 + 1/R2 + 1/R'2 \ ) \qquad\qquad (\ 1 \ ) \ . \ .$$

$$B - A = 1/2 \ [(\ 1/R1 - 1/R'1 \ )^2 + (\ 1/R2 - 1/R'2 \ )^2$$

$$+ \ 2 \ (\ 1/R1 - 1/R'1) \ (\ 1/R2 - 1/R'2) \ Cos \ 2\psi \ ]^{1/2} \qquad (\ 2 \ )$$

In the case of two chain links R1 = R2 = R and R'1 = R'2 = R'

and ψ = 90 ; (1) and (2) become

$$A + B = 1/R + 1/R' \qquad\qquad (\ 3 \ )$$

$$B - A = 0 \quad A = B \qquad\qquad (\ 4 \ )$$

The contact pressure between the links is semi-elliptical with the major (2a), minor (2b) axis and maximum contact pressure (q_0); where a and b are calculated from:

$$(\ 5 \ )$$

$$a = m \ [\ 3 \ \pi \ P \ (\ K1 + K2 \ )/ \ 4 \ (\ A + B \ ) \ ]^{1/3}$$

$$b = n \ [\ 3 \ \pi \ P \ (\ K1 + K2 \ )/ \ 4 \ (\ A + B \ ) \ ]^{1/3} \qquad (\ 6 \ )$$

in which m and n are numbers depending on the ratio (B−A)/(A+B);

$$Cos \ \theta = (\ B - A \ )/(\ A + B \ )$$

For two links $Cos\theta$ = 0 $\Rightarrow$ θ = 90 ; from the table [121] m=n=1

also K1 = K2 = (1 - ν)/ π E: where ν, Poisson's ratio, E

, Young's modulus. P is the applied load in the links.

The maximun contact pressure, $q_0 = 3*P/2\pi a\,b$ (7)

There are two cases to be considered in contact pressure evaluation:

a) Mining chain

$R1 = R2 = 9.5$ mm

$R'1 = R'2 = -12.75$ mm

Substituting   (3) and (4)

$A + B = .0268$

$A = B$

Hence, $A = B = .0134$

For $E = 209$ GPa and $\nu = .3$; $K1 = K2 = 1.386$ E-6 ;

(5) , (6) and (7) become

$a = b = .06246\ (P)^{1/3}$

(contact area is a circle with radius a)

$q_0 = 122.38\ (P)^{1/3}$

Contact angle is the internal angle subtending the contact region.

i.e. $12.75\ \alpha = a$

Contact angle (α) is $\alpha = 4.4938\ a$ (in degrees)

b) Lifting chain

$R1 = R2 = 3.45$ mm

$R'1 = R'2 = - 5.55$ mm

Similarly

$A + B = .1097$

$A = B$

$A = B = .0548$

$a = b = .03905\ (P)^{1/3}$

$q_0 = 313.14\ (P)^{1/3}$

Contact angle (α) is $10.3236\ a$ (in degrees)

The values of a, q_0 and α are given in Table 7.1 for both cases.

The maximum contact pressures are so great that there must be plastic

flow.

7.3 PLANE STRESS/STRAIN ANALYSIS

Often in stress analysis, a full three dimensional treatment of a
problem can be avoided by assuming the structure to be adequately
represented if plane stress or plane strain conditions adopted.
Historically, plane solutions were the first attempted by the finite
element method. The basic definitions and applicable expressions can
be found in many standard text books on the theory of elasticity (e.g.
[127,128]) and only a brief outline of the assumed conditions is
included here. A fully three dimensional situation reduces to a two
dimensional problem if all quantities are independent of one of the
coordinate directions, usually assumed be the z-axis. Furthermore,
for a planar condition to exist, all body forces and surface forces
acting on the solid must act in the xy plane (i.e. have no z
component).

a) PLANE STRAIN

If, in addition to the above assumption, the normal strain in the z
direction, ε_z , is zero then a plane strain condition is said to
exist. In this case the only non-zero stress components are the
in-plane components σ_x, σ_y, τ_{xy} and the
through-thickness stress σ_z. All the equations of elasticity
are satisfied and this is an exact theory within the framework of
three dimensional elasticity. Conditions of plane strain usually
occurs if the thickness of the solid (in the z-direction) is large in
comparision with the representative x and y dimensions.

b) PLANE STRESS

On the other hand, it is assumed that the normal stress in the z-direction ,σ_z, is zero, a plane stress condition exists. In this case the in-plane stress component, σ_z, σ_y, τ_{xy} are again non-zero together with the normal strain component, ε_z. This is an approximate theory since the limitations placed on the variation of the ε_z strain over the xy plane cannot generally be satisfied and τ_{xz} and τ_{yz} are non-zero. However it is assumed that they can be neglected for analysis. The body is thin (i.e. it is small in comparision with the representative x and y dimensions). Also there are no surface forces acting on the end faces (z = $\pm$ t/2).

7.4 INTERFACE ELEMENTS FOR STRESS ANALYSIS

These elements are available for modelling surface interface conditions, principally the gap/friction interface. The elements are provided with an interpolation or shape function that is compatible with the various elements in the program,so that an appropriate choice can be made to match the element chosen for the modelling on each side of interfaces.

Typical elements are shown in Fig. 7.1 a. First a load system is constructed for reporting shear and pressure stresses between the surfaces (if they are in contact), as well as the relative displacements of corresponding points. It is assumed that the nodes on the opposite faces of the interface elements are matched in position and that this local system does not rotate during the motion. The local directions normal and tangential to the interface can be

specified directly [38] or calculated by the program. If the latter
option is chosen the local system is based on the average interface
surface, found by taking the average of the coordinates of
corresponding nodes on the surfaces of the bodies A and B (Fig. 7.1
b):

$$x = 1/2 \ (\ x_{NA} + x_{NB} \ )$$

The 'average interface surface' is then constructed using the
element's interpolation function and these positions. The normal is
defined as the normal to this average interface surface, pointing from
surface A to surface B. If the average normal direction does not give
the correct definition of the normal direction, it ought to be
specified using *NORMAL (a module in the software to specify the
normal direction) option.

The program calculates the initial clearance between the surface at
each calculation point from the coordinates specified for the surface
nodes forming the interface elements. Thus, if the clearance is
small, these coordinates should be given to sufficient accuracy. The
stress calculation points are always between the corresponding node
pairs of the two surfaces. Then at each such point, the program
determines if the two bodies are touching or not, based on the
relative positions of corresponding points of the nodes of the two
surfaces, projected on the normal direction. If the bodies are not
touching, no forces are transmitted at this point. If they are
touching, the appropriate surface theory is applied to model the force
transmission.

The surface theory presently implemented in the program is a classical
Coulomb friction law: the surfaces slide when the shear stress

between them tries to exceed the coefficient of friction times the normal stress. The coefficient of friction is assumed to be constant. For perfect sliding , coefficient of friction $\mu = 0$; the surfaces lock in shear as soon as they touch when μ is very large (e.g. 1.E10).

7.5 19 mm MINING CHAINS

Plane stress/strain analysis of chains in contact is the second most economical analysis after the beam analysis (Chapter 6). To carry out this analysis it was necessary to model only a quarter of the 19mm mininig chain because of geometrical and loading symmetries. The mesh, Fig. 7.2, consists of 90 eight-noded quadratic isoparametric plane stress/strain elements with 16 three noded one dimensional interface elements. The mesh is very fine in the region of contact to be able to detect very closely, the effect of contact on the contact area, pressure, and deformations. The refinement was carried out using the facility called Multipoint Constraint (MPC) in the software, ABAQUS [38,39]. This allows the analyst to go from one element to two in two and three-dimensions by constraining the appropriate nodes [129]. It is a very efficient way of mesh refinement and details can be found in the ABAQUS User's Manual. The mesh is constrained at the centre of the barrel is the y-direction and at the crown in the x-direction. A uniform pressure was applied to the face of elements lying at the centre of the internal link in the y-direction. The magnitude of this pressure is twice the nominal stress at the centre of the barrel due to differential areas. This application of load is more realistic than a point load at the centre of internal link [44,45,46].

Geometrical nonlinearity was also considered with convergence
tolerance ranging from .5 % and 1.% and automatic incrementation.

7.5.1 TOTAL STRESSES

The model described earlier was analysed elasto-plastically with the
same material model as in Chapter 6. Plane stress and plane strain
analysis were carried out at various calibration loads and up to
failure. Fig. 7.3 shows the various stress contours (plane stress
case) for cl= a)260 kN, b) 320 kN, c) 380 kN and failure load of 497
kN. As the calibration load increases, the stresses at the outside
barrel increase and it falls as soon as the link starts failing. This
is also indicative of yielding taking place as the calibration load
increases. The stresses around the contact region increase with
increase in calibration load. To obtain a clear picture at the
boundaries (inside and outside), the stresses (largest absolute
principal stresses) are plotted, Fig. 7.4 and 7.5 for both plane
stress and plane strain.

At the outside, the stresses at the barrel are compressive and range
from 500 to 1500 MPa depending on the calibration level; whereas
stresses at the crown are tensile and range from 1000 to 2000 MPa.
Plane stress and plane strain analysis both give similar stress
pattern with plane strain stresses rather high, Fig. 7.4. At the
inside, the opposite is true, i.e. stresses at the barrel are tensile
and crown are compressive. Similar patterns exist for both analyses
with plane strain resulting in rather high stresses, Fig. 7.5. The
stresses resemble the results from the beam analysis (Chapter 6) at
the outside and inside.

The deformation at various calibration levels and failure load are given in Fig. 7.6 for plane stress case. With increase in load, the links get pulled in at the barrel and extended out at the crown. Consequently, the contact and penetration between the links increases. This will be investigated in the next section.

7.5.2 CONTACT PRESSURE AND AREA

Implementation of interface elements in two dimensional plane stress/strain analysis of chain resulted in the evaluation of contact between the chain links. The contact starts with a point at the crown and as the load builds up, the contact points increase to 2, 3, and so on. The extent of contact pressure and area for both elastic and elasto-plastic materials are considered below:

A) Elastic material

The contact pressures at the surface of contact along the outer link are give in Fig. 7.7 at various load levels for plane stress and strain conditions. The pattern for both cases is the same and is that of approximately quarter of an ellipse, which is expected theoretically for two links in contact, as established earlier (Section 7.2). Similar variation in contact angle and pressure exist between them with somewhat higher values in the case of theory. The theoretical result does not take into account any deformation of the link as a whole, whereas in fact the load tends to reduce the radius of curvature of the link, increasing the area of contact and reducing the pressure. Plane strain analysis results are rather higher than plane stress case at various calibration loads.

B) Elasto-plastic material

Fig. 7.8 illustrates the results for this case. The contact pressure remains constant just over yield stress, and shoots up just before falling to zero (plane stress). Similarly, the plane strain behaves the same with a constant pressure of higher magnitude. With an increase in calibration load, the plane strain analysis gives higher contact pressures and correspondingly smaller contact areas than the plane stress analysis (Fig. 7.9). The contact ceases to exist between the links at about 53.45 degrees at the outer link, as the inner link starts to wedge into the outer link. The extent of contact area varies of course with load, Fig. 7.9.

7.5.3 RESIDUAL STRESSES

The chain model was loaded up to calibration loads automatically and unloaded to give the residual stresses. This was achieved in 28, 44 and 40 increments as the calibration load built up. The Von Mises residual stress contours are given in Fig. 7.10. At the first calibration load there is about 200 MPa residual stresses at the barrel and crown with larger variation at higher calibration loads.

In the region of the crown, on the inside, the residual stresses predicted for plane stress conditions are tensile, whereas for plane strain conditions they are largely compressive (Fig. 7.11). The stresses in the barrel for the plane stress condition are higher for lower calibration loads with no significant change at the largest calibration load, Fig. 7.12.

There is a significant variation in the residual stress distribution

at the inside of chain link with higher tensile stresses at the crown
(for plane stress) than that of in plane strain. The stresses at the
barrel are all compressive with lower values for the plane strain
condition, Fig. 7.11.

Overall, the residual stresses at the boundaries of the chain link are
compressive with larger magnitude at the inside of the shoulder and at
the outside of the barrel except at the contact zone (tensile). They
also increase with an increase with calibration load and resemble the
results from the beam analysis (Chapter 6).

7.6 7 mm LIFTING CHAIN

The mesh with element numbering is given in Fig. 7.13 for the 7 mm
lifting chain with elasto-plastic material properties as in Chapter 6,
(Section 6.4). Similar analysis as the mining chain (previous
section) was carried out in plane stress condition only and the
results are presented below:

The Von Mises stress contours are given in Fig. 7.14 at various
calibration loads, and stresses (largest absolute principal stresses)
at the inner and outer surface are given in Fig. 7.15 and 7.16, and
deformation at Fig. 7.17. Before the chain fails at 64 kN, the
stresses drop dramatically at the inside barrel and outside crown.
Otherwise, the stresses behave as expected - with higher calibration
loads resulting in higher stresses.

The plastic contact pressure remains steady with lower pressure at
failure stages, Fig. 7.18. The elastic contact pressure variation is
also included in Fig. 7.18 (Comparing with Table 7.1), highlighting

the effect of considering plasticity. The contact angle versus
nominal pressure at the central barrel is given in Fig. 7.19,
indicating an almost a linear relationship.

The residual stresses are given in contour form (Von Mises Stresses)
and plots at inner and outer boundaries of the chains, Fig. 7.20,
7.21 and 7.22. No significant residual stresses are introduced by the
first calibration load except at the region of inside barrel and
crown. But as the calibration loads increase, the residual stress
distribution changes dramatically (b and c). Similar behaviour
appears at the boundaries with a drop for the third calibration load
at the outside barrel. Again the stresses at the boundaries are
compressive except at the inner contact region and are comparable to
those obtained using the beam analysis (Chapter 6).

CHAPTER 8

FINITE ELEMENT STRESS ANALYSIS OF CHAINS (3-D)

8.1 INTRODUCTION

Soon after the emergence of the finite element method for analysis of linear elastic structural problems, it was further developed to be used for nonlinear problems. Initially, in the mid-sixties, these developments were concerned with the implementation of nonlinear constitutive equations in finite element codes which had been designed for linear elastic analysis [130], quoted in [131]. Therefore, geometric nonlinearity was also included in the finite element analysis methods, and again the starting point for such nonlinear analysis was linear elastic finite element analysis [131].

The researchers who carried out these analyses generally thought of their nonlinear problems as modified linear problems, which resulted in a solution method called the initial stress (strain) method, nowadays known as modified Newton-Raphson method. Another type of method which emerged was to see nonlinear problems as a series of linear problems, to be solved sequentially. This is the so-called the tangent modulus method, nowadays recognised as the full Newton-Raphson method. Various other nonlinear solution methods have since been developed and are discussed elsewhere [127,132,133,...].

There are problems in which the above types of nonlinearity are combined. A paper by J.C.Negtegal [131] discusses this topic well in detail. There are two classes of combined nonlinear problems. One type of problem is the geometric instability problem with material nonlinearity. In this problem, the main nonlinearity is of a geometric nature and is supplemented by nonlinear material behaviour. A typical example of such a problem is a spherical cap with ring load. The second type of problem is characterised by large scale material

nonlinearity, which has as a consequence that geometric nonlinearity must also be taken into account. Typical areas in which this situation arises are the analysis of metal forming problems and the analysis of chain links under loads, such as to cause plastic yielding: the latter is the subject of this research work. The finite element formulation, constitutive equations, element selection and solution procedure are all given in the ABAQUS theory manual [39] as well as in some standard text books [127,134].

The following preliminary general considerations apply to the finite element analysis of chains:

a) Load incrementation - one of the difficulties encountered in any nonlinear incremental-iterative solution scheme is the choice of load increment. An improper choice of load increment may result in an expensive iteration or convergence may never be achieved. Thus from economical point of view, the automatic incrementation option should be used when the solution is not known (in the case of chain analysis to failure), and manual incrementation when the solution is either known or can be predicted (in the case of calibration of chains).

b) Convergence criterion - at the end of each iteration, the solution is checked to see whether it has converged or diverged within pre-set tolerances. A convergence tolerance that is too loose results in an inaccurate solution and one that is too tight results in needless accuracy. Hence, in this study, a realistic convergence tolerance was taken in the range of 0.3 % to 1.0 % for load and moment tolerances.

c) Analysis termination criterion - there are two criteria to end an incremental-iterative scheme. Firstly, the failure of a structure

takes place when no further loading can be sustained. This is provided for in ABAQUS when the load increment becomes smaller than 0.001 percent of the applied load (as is the case in all failure load determination). Secondly, the failure of a structure makes the convergence difficult to satisfy in a specified number of iterations. This is implemented in ABAQUS and 20 iterations were used throughout this chapter.

In this chapter a complete three dimensional analysis of chains will be carried out with a realistic pressure distribution due to contact (considering the observations in Chapter 7) between chain links. First, the contact pressure assumption will be disscused in detail, (Section 8.2). Then, the mining chains (19 mm circular and 22 mm oval cross-section) will be analysed to examine the effect of changes in link geometry on the stress pattern under elastic and elasto-plastic conditions during calibration and loading to failure (Section 8.3). Finally, the lifting chain will be considered under similar loading conditions to those of mining chains (Section 8.4).

8.2 CONTACT PRESSURE ASSUMPTION

In the three-dimensional finite element analysis of chains, the modelling of loading is as important as geometrical modelling which will be discussed in the next section. From the theory of two elastic bodies in contact ([121], Chapter 7) the contact pressure envelope is ellipsoidal. In the case of plasticity, this will not be the case, as was shown in Chapter 7 for the two-dimensional contact. The ideal envelope can be found by application of three-dimensional contact analysis, which was not possible in the course of this research. But a compromise was made in assuming a contact pressure envelope by

taking into account the elastic contact envelope and the two-dimensional contact analysis results. The assumed contact envelope is shown in Fig. 8.1 for chains of oval and circular cross-section. In both cases, the assumed envelope (with a pressure of some 3000 and 1000 MPa) is applied at the surface of elements refined at the inside of the link crown, shown in Fig. 8.2, where the contact occurs.

With the above envelope, the sizes of the elements in the refined zone were changed (by altering the angles ϕ and ψ). ϕ and ψ are the subtended angles of contact at the crown in the z and y-directions respectively, Fig. 8.2. In each case an elastic finite element analysis was carried out to determine the reactions at the centre of the link (in the y-direction) for evaluation of applied load. The angle ϕ was then plotted against the applied load. The results of similar analyses for all ϕ, considered in this research, are given graphically in Fig. 8.3. The size of the elements can be adjusted from this graph to achieve any particular load (by choosing appropriate values of ϕ and ψ). Table 8.1 shows the corresponding values of ϕ and ψ for all the grades of chains at various load levels. It also shows the contact angle for 19 mm mining and 7 mm lifting chain from the two-dimensional contact analysis (Chapter 7): at low loads the values are comparable with those assumed in the three-dimensional analysis but are somewhat larger at higher loads. The relationship between ϕ and ψ is given by:

$$R_1 \psi = R_2 \phi$$

(R_1 is the inner radius of the link at the crown and R_2 is the radius of cross-section of the link).

8.3 MINING CHAINS

High-tensile steel chains are used in mining equipment to transport coal from the mine face to the surface, hence the name "mining chain". Their size varies from 14 to 26 mm diameter. In this research, 19 mm diameter and 22 mm oval cross-section (oval-link) mining chains were investigated. The configuration of both types of chains are given in Chapter 5 (Fig. 5.2 a). Geometries (eight-shape and elliptical) different from that of standard chains will be disscused in Section 8.3.1 and the oval-link chains will be considered in Section 8.3.2.

8.3.1 19 mm MINING CHAINS

A full three-dimensional stress analysis of chains was undertaken to understand the state of stressing under both calibration and service loading as well as to determine the residual stress distribution . resulting from the calibration processes. The finite element formulation of the problem was omitted but can be found in the ABAQUS theory manual [39] as well as in the standard text books on the subject [127].

It was necessary to model only an eigth of the chain link because of geometrical and loading symmetries. A suite of programs -
in the Pascal programming language was developed to generate the mesh by choosing appropriate values of the parameters (Fig. 8.2 and Fig. 5.2 a).

R1 - internal radius at the crown,

R2 - radius of the chain link,

L - half the barrel length,

M1 - number of segments in the barrel,

M2 - number of segments in the shoulder (exclusive of 6 segments in the refined zone),

θ – angle of straightness (=0,+24 and –24 for the standard, eight shape and elliptical),

φ – angle of refined zone at the section through the crown,

ψ – angle of contact.

Solid elements with 20 or 27 nodes with reduced integration were chosen: these use a lower order integration to form the element stiffness. This can usually provide improved accuracy and significantly reduces running time in three-dimensional analysis. The multipoint constraint (*MPC) facility was used to refine the mesh in the region of contact between chain links, as proposed in Section 8.2. Application of multipoint constraint (MPC) for three-dimensional elements can be found in the ABAQUS manual [38,39,40]. The formulation of the multipoint constraint is also covered by Ang et al [129]. *MPC enables mesh refinement to be produced by permitting two smaller elements to be in contact with one larger element on one face of the latter.

The mesh is constrained at the centre of the barrel in the y-direction, at the crown in the x-direction and at the midplane in the z-direction. The required loading may be applied using the procedure established in Section 8.2 (i.e. by generating a mesh with appropriate parameters).

Geometrical nonlinearity was also considered in all the analyses with convergence tolerances of 0.3 % to 1.0 % with either automatic or manual incrementation, depending on which was suitable. The same material model as in Chapter 7 was used with calibration loads of 260 kN, 320 kN and 380 kN.

8.3.1.1 MESH REFINEMENT

In finite element stress analysis, the solution depends on the mesh
size, i.e., the finer the mesh the better the results are up to a
point. But finer meshes result in longer running times, hence a
compromise needs to be made. In this section, the effect of mesh
refinement on the total and residual stresses was investigated with
the intention of arriving at an optimum number of elements to achieve
the best solution.

Two parameters (M1 and M2), the number of slices in the barrel and in
the shoulder respectively, Fig. 8.2, were chosen as follows:

a) M1 = 1 and M2 = 1

b) M1 = 3 and M2 = 2

c) M1 = 6 and M2 = 4

Loading of 320 kN (its equivalent pressure) was applied in all three
cases with the boundary conditions and material properties given in
Section 8.3.1. The residual stresses were found by taking the model
through a loading-unloading cycle. The total and residual stresses at
the inside and outside of the model are plotted in Fig. 8.4 and 8.5
for all the mesh sizes. It can be seen that the residual stresses in
case (a) are very different from those in cases (b) and (c), which are
virtually the same. The total stresses also behave in a similar
manner. Since the refined zone was kept unchanged, the total and
residual stresses were the same in that region in all cases
considered. Hence, case (b) is the optimum case giving a shorter run
time than case (c) and results that are in agreement with the more
precise results to be expected from the more refined mesh (c).

8.3.1.2 ELASTIC STRESSES

Elastic stress analysis was carried out for all geometries (standard, eight shape and elliptical) whose meshes are given in Fig. 8.6 (a,b and c). The elastic stresses are given in Fig. 8.7 for the outside and inside the links. The stress distribution is similar to that in which a point load was applied at the crown [45,46]. Overall, the eight shape link has the lowest stresses except at the inside transition (largest); the elliptical link has the largest stresses with the exception of inside transition; the standard link seems to have stresses intermediate between those of the other two geometries.

8.3.1.3 TOTAL STRESSES

The finite element elasto-plastic analysis of all the geometries was carried out for all the calibration levels and also to failure. The total stresses are plotted at the inside and outside for all the geometries and for all the load levels, Fig. 8.8 to 8.15.

The total stresses at the inside of the links are tensile in the barrel and some part of the shoulder, and increase with increasing calibration load, Fig. 8.15. The stresses at the inside crown are compressive with large magnitude resulting from the local pressure loading. The overall stress pattern is the same as the elastic stress pattern.

The total stresses at the outside of the links are compressive in the barrel and some part of the shoulder and tensile at the crown of the link, Fig. 8.14. As the calibration load increases, more yielding of the link takes place, and when the fracture load is reached, extensive yielding has taken place.

In agreement with experimental results, the numerical analysis indicates that the links with different geometries will fail at different loads (Table 8.2). The failure load of the elliptical link is very closely predicted by the finite element method, whereas the failure loads of the standard and eight shape links are underestimated by 6 % and 8 % respectively.

The mesh for the elliptical link under failure load was generated with a modified version of the mesh generating programe for the standard and eight shape links.

8.3.1.4 RESIDUAL STRESSES

The residual stresses were found by taking the models through a loading-unloading cycle. The loading was achieved by 15 equal increments ,and the unloading by 5. The inside and outside residual stress distributions are presented below:

The residual stresses at the inside are given in Fig. 8.16 to 8.19. They are compressive along the barrel except for the eight shape link which exhibits some tensile stress at the beginning of the barrel. The stresses at the refined area and nearby are tensile. The stress patterns appear to be the reverse of the total stresses (Section 8.3.1.3) Fig. 8.19.

The residual stresses at the outside are given in Fig. 8.20 to 8.23. They all are compressive with varying degree of magnitude and there is no variation in the stresses at the crown due to different geometries, Fig. 8.23. The residual stresses ,in general, increase as the calibration load increases, but some variation exists in some cases.

The total and residual stresses at the crown do not vary as a result of geometrical changes except at the inside zone (due to the application of pressure at this zone), Fig. 8.24. The variation due to geometry can be seen in Fig. 8.25 for the centre of the link. Residual stresses for the standard link geometry at the centre are in good agreement with the results obtained from the neutron diffraction work (Chapter 4), with appropriate material models and the pattern is the same as in Fig. 8.25. The stresses at the sections through the centre of the barrel and crown both correspond to the calibration load of 320 kN.

8.3.1.5 BEHAVIOUR OF STRAIN GAUGES NO. 3 AND 10

In the strain gauge work discussed in Chapter 5, it was found that the strain gauges numbered 3 and 10 ,positioned at 60 degrees to the crown, behaved very oddly. That is to say when the links were being unloaded, the strains at these gauges increased (in some cases) rather than decreasing as expected. This phenomenon was investigated using the finite element analysis of the all three geometries. The results of the analysis are plotted either for the same position as gauges 3 and 10 or positions on either side of the gauges. In Fig. 8.26, the strains in the y-direction are plotted for a loading-unloading cycle. Similar variations in strain are also observed in the x and z-directions. The anomaly occurred in three cases :

a) For the elliptical shape link

b) For the standard link if the gauge is slightly closer to the crown than its designed position.

c) For the eight-shape link if the gauge is slightly closer to the crown than its designed position.

A slight discrepancy in the gauge position is entirely possible, since
the installation of the gauges exactly on the marked position is very
difficult and also the marking of the position involves inaccuracies
because of uneveness in the link caused in the manufacturing process.
It may thus be concluded that the numerical analysis has reproduced,
at least qualitatively the anomaly observed experimentally. The same
conclusion may also be arrived at by considering the largest absolute
principal stresses plot verses loading, Fig. 8.27.

8.3.2 22 mm MINING CHAINS (OVAL-LINK AND EQUIVALENT CIRCULAR CROSS-SECTION LINK)

The heavy-duty oval-link chain was designed to allow a stronger chain
to be used in a panline of specified size (Fig. 2.3). For example,
the 22 mm pan line originally designed to accommodate either 22 mm
twin outboard or 26 mm twin inboard chain assemblies of the
conventional type, will, with the development of the oval-link mining
chain, now be capable of utilising 26 mm twin outboard and 30 mm twin
inboard assemblies, creating obvious savings in pan line costs,
weights and heights [135].

The oval-link and its equivalent circular cross-section link with the
same inner radius at the crown and the same barrel length and
cross-sectional area were analysed using the finite element method and
the results are presented in the following sections. The mesh for the
oval-link was generated using another Pascal program (Fig. 8.28),
while the equivalent link was generated with the original program.

8.3.2.1 ELASTIC STRESSES

The mesh of Fig. 8.28 was loaded in two ways using either:

a) a point load at the crown

b) the contact pressure envelope established earlier (Section 8.2)

The elastic stresses corresponding to the first calibration load (393 kN) are given in Fig. 8.29 for the inside and outside the link. The stresses at the top layer and bottom layer (Fig. 8.28) of the oval-link are identical in both cases: hence, only the top layer stresses are given except in the region of contact, where the top layer experiences higher stresses under the immediate prescribed loading pressure. Higher stresses are experienced when the point load is applied, Fig. 8.30 and 8.31; stresses are ignored at the region of application of the load. Since the modelling is here unrealistic. Furthermore, the stresses of the equivalent link are higher than those of the oval-link when either a point load or a contact pressure. . envelope was applied, Fig.29.

8.3.2.2 TOTAL STRESSES

The stresses at the inside and outside are shown in Fig. 8.32 given by a complete finite element analysis of the oval-link for two calibration loads, 393 kN and 489 kN,and for the failure load. The stresses generally increase with the increase in the applied load for both the inside and outside the link.

Similar results occurred in the case of equivalent link, Fig. 8.33. The total stresses for the equivalent link are given in Fig. 8.34. The link behaviour under calibration load of 489 kN is shown in Fig. 8.34 for elastic and elasto-plastic analysis. The barrel and outer crown yielded completely, whereas in the elastic state, the inside-barrel stresses are well below yield stress (Section 8.3.2.1).

The total stresses are given in Fig. 8.35 and 8.36 under the first calibration load and the failure load. The oval-link underwent smaller stresses than its equivalent under the first calibration load, Fig. 8.35, while at failure, the stresses in the oval-link are larger at the outside barrel and lower at the crown than those of the equivalent link, Fig. 8.36. The failure load of the oval-link was predicted to be 546 kN, 3.4 % lower than that of the equivalent link. The actual failure load of the oval-link was 606 kN, the numerically predicted figure being 10 % less.

8.3.2.3 RESIDUAL STRESSES

The residual stresses were found by taking the models through a loading-unloading cycle. They are plotted for the inside and outside of the links, Fig. 8.37 and Fig. 8.38 . With an increase in calibration load, the residual stresses also increase in the case of both links. This is very significant in the oval-link. The stress pattern remains the same for both links, although they have different cross-sections. For both links , the peak stresses are positioned just after the transition zone at the inside and are roughly equal to the largest stresses at the outside the link. Such higher compressive residual stresses at the transition zone are very desirable.

Fig. 8.39 illustrates the residual stresses caused by the calibration load of 393 kN for the two links. The equivalent circular cross-sectional link has larger stresses than those of the oval-link at the inside whereas the oval-link has larger stresses along the outside of the barrel.

The stresses in the refined zone and nearby are invalid because of

application of pressure and ought to be ignored.

The total and residual stresses are given through a section at the centre and crown for the two links under a calibration load of 489 kN, Fig. 8.40 and Fig 8.41. There is no difference between the two at the centre, but some difference at the crown, where the pressure was applied - at the start and end curve (invalid results because of load application).

8.4 7 mm LIFTING CHAIN

Three-dimensional stress analysis of 7 mm lifting chain was carried out with the material properties given in Chapter 7 and with the same boundary conditions as for the mining chains. A mesh with 3 and 2 slices at the barrel and shoulder of the link was considered with a refined zone for contact pressure implementation. First an elastic analysis was carried out with stresses shown in Fig. 8.42 at the inside an outside the barrel. The model was then loaded up to calibration loads elasto-plastically to compute the total stresses. It was also loaded up to failure load (64 kN) and the stresses are given in Fig. 8.43. Finally the unloading was completed to give the residual stresses, Fig. 8.44.

Total stresses increased with increase in calibration load. Similarly, the residual stresses increased, except for the third calibration load, in which case, the stresses do not appear to have changed significantly at the outside the barrel with increasing calibration load, Fig. 8.44.

Fig. 8.45 to 8.47 give the stresses through section at the centre,

transition and crown to help in interpreting the effect of calibration load on fatigue failure. The total and residual stresses have the same pattern at the transition and centre sections, differing at the crown. The effect of increase in calibration load is very significant at all three sections.

8.5 OTHER ASPECTS OF LINK GEOMETRY

So far during this research only cross-sectional and overall link geometries such as inward or outwardness of the links have been considered. Other aspects of the link geometry such as increase in barrel length (pitch) and internal radius at the crown have not been been investigated. In this section a thorough understanding of the above mentioned parameters will be attempted for the 19 mm standard mining chain.

8.5.1 INTERNAL RADIUS AT THE CROWN

Barrel length of the standard 19 mm mining chain was kept constant at 17 mm and only the internal radius at the crown was allowed to change (9.5, 12.7 and 16 mm). The model was loaded with the pressure distribution established earlier (Section 8.2). A complete elastic and elasto-plastic analysis of the link was carried out for all three cases and the stresses at the boundaries (outside and inside) were plotted, Fig. 8.48 and 8.49. The stresses were raised by the increase of internal radius as expected, but considerable rise was not achieved in the elasto-plastic analysis except at the tensile peak position at the inside of the link. Most importantly, the peak tensile stress position was moved towards the crown with the increase in internal radius. Residual stresses were also obtained by taking

the models through the loading-unloading cycle and are given in Fig. 8.50 and 8.51 at the outside and inside of the links for calibration load of 320 kN. The residual stresses decreased with increase in internal radius. The internal radius of 9.5 mm is the optimum radius as far as the total and residual stresses are concerned, but it is not practical because of the interlink configurations. Hence the second best radius (R1=12.7), given in the British Standards Specifications for this grade of chain is a satisfactory practical choice.

8.5.2 BARREL LENGTH (PITCH)

Three different barrel lengths were chosen for a fixed internal radius at the crown (12.7 mm): L= 10, 17 and 27 mm. From the elastic and elasto-plastic analysis of all three cases the stresses were plotted, Fig. 8.52 and 8.53. With increase in barrel length the total stresses were decreased in the elastic analysis and was unchanged in the elasto-plastic analysis. However the effect on the residual stresses are significant, Fig. 8.54 and 8.55. The barrel length of L=17 mm (given in the British Standards Specifications) is optimum as far as the total and residual stresses are concerned.

On the whole, the British Standards Specification for the 19 mm mining chains has the optimum dimensions as far as the total and residual stresses are concerned for given link diameter.

CHAPTER 9

GENERAL DISCUSSIONS

9.1 INTRODUCTION

In this work various experimental stress measurement techniques such as: x-ray, neutron diffraction and strain gauge methods were used to determine stresses in the 7 mm lifting chains, 19 mm mining chains and 22 mm oval-link mining chains. In addition to the experimental work, FE was also used to compute the corresponding stresses which were either total (under calibration loads) or residual (as a result of calibration). Lastly, an extensive amount of fatigue testing of 7 mm lifting chain was carried out with some related direct stress tests on chain material specimens to show the effect of mean stress on fatigue properties of the chain material. Some of the above results were discussed under relevant headings and only the important overall features will be included in this section with special emphasis·on the potential benefits of differential heat treatment of chains.

9.2 7 mm LIFTING CHAIN

FE stress analysis of the 7 mm lifting chains gave the stresses under the calibration loads and the residual stresses as an end result of these loads. These stresses were obtained from various models, ranging from a simple beam analysis (1-D) through contact analysis (2-D) to three-dimentional (3-D) stress analysis. The stresses from all three different analyses confirmed the existence of residual stresses as a result of calibration, the predicted magnitudes of the residual stresses being similar. Discrepancies are, of coures, expected because of the different theoretical modelling of the link and its loading, but overall the results are consistent.

The x-ray measurements of the residual stresses also confirmed the

existence of the residual stresses, largely as expected from the FE work, as well as the effect of increased calibration loads on their magnitude. The stresses at the outer surface of the 7 mm lifting chain were all compressive with larger magnitudes in the middle region of the side and at the crown of the links.

The effect of residual stresses on the fatigue properties of this grade of chain was demonstrated by fatigue testing results (Chapter 3). Fatigue lives of the links were improved dramatically by calibration: up to tenfold depending on the degree of calibration. A calibration load of 20 kN (25 % over working load limit) did not have any significant effect on the fatigue lives since it was insufficient to cause plastic deformation. The effects were very much more apparent with calibration loads of 30, 38.5 and 50 kN. The. upper bound for the calibration load for conformity with existing standards is 56 kN, which was calculated using the concept of energy absorption factor (Appendix A); in other words, the 50 kN calibration load chosen in the testing is permissible. Similar improvements were achieved in the testing of the chain material, in which the presence of residual stresses was simulated by a variation in mean stress. The results may be represented by reference to the concept of the Goodman diagram. The fact that the calibration of chains introduces residual compressive stresses at their surface produces a reduction in mean stress, which results in higher fatigue lives, in accordance with the Goodman diagram (and the experimental fatigue specimen results).

9.3 19 mm MINING CHAIN

A complete FE stress analysis was carried out on the 19 mm mining chain of different shapes (standard, eight shape and elliptical) and

22 mm oval-link mining chains. Experimental stress measurements on these links were carried out using x-ray, neutron diffraction and strain gauge techniques to establish confidence in the FE results.

The link, slowly cooled after tempering, did not appear to exhibit surface residual stresses. Water quenching after tempering gave rise, as expected, to surface residual compressive stresses. However, calibration (required to raise the load to which the chain behaves elastically) caused modification of these stresses so that the effect of water quenching was effectively lost.

The neutron diffraction technique also confirmed the existence of residual stresses within the the link, with compressive stresses in the outer layer and tensile in the central region. Satisfactory quantitative agreement with the FE work was obtained. Strain gauge work also confirmed the residual stress pattern obtained by the other methods and was in good agreement with the FE calculations during loading, both under initial elastic conditions and also after yielding.

The x-ray results clearly demonstrate the effect of increase in calibration load in increasing the magnitude of the residual stresses. The neutron diffraction work is particularly informative in that it provides quantitative confirmation of the FE results at positions within the body of the link. The results of the FE analysis of residual stresses might be made slightly more realistic by introducing the possibility of inelastic behaviour during unloading, which could not be modelled at the time this work was done.

In the study of the optimum link geometry, to examine the way in which

link shape affects the load before plastic deformation begins in the uncalibrated condition, the following alternatives were considered: different link shape (standard, eight shape and elliptical), link length, inside link diameter and oval cross-section (as opposed to the usual circular cross-section). In fact, the oval-link gave the highest value of nominal stress at yielding. As the service stresses are the summation of the residual and the stresses which would be produced if the links were loaded elastically, optimum link shape depends on whether a link is calibrated or uncalibrated. It also depends on the level of calibration and the applied load which may determine the fatigue fracture position (provided the link is not loaded beyond the calibration load). It is in fact found that the standard 19 mm mining chain link is the optimum shape as regard to the combination of the elastic stresses under load and the residual stresses; the oval-link geometry is advantageous in contrast to the circular cross-sectional link regarding elastic stresses only, whereas the situation is reversed considering residual stresses. Further general remarks will be made in the conclusions (Chapter 10) with respect to the link length and inside diameter.

Anomalous strain gauges results (strains rising as the links were unloaded, Fig. 8.26 and 8.27) were obtained in determining residual stresses (Chapter 5). Similar anomalies were produced using the FE method indicating that some area at the position of strain gauges placed at 60° to the crown is behaving in this manner for standard, eight shape and elliptical shapes. This position is very close to the point which the maximum absolute principal stresses change from compressive to tensile, Fig. 9.1. Elastic FE analysis in which geometric changes are ignored gave a slightly different change-over position from that given by large-deflection elastic

analysis - but in the latter case the position remained unchanged with load. It had been thought that the anomaly might be connected with movement of this point during unloading, so that a change from, say, tension to compression at the gauge as a result of movement of the change-over point, would mark the expected change in strain during unloading. The FE results do not appear to support this hypothesis, however, and the cause of the anomaly remains unclear. During loading, the gauges involved also show a change in sign of the strains when plastic deformation sets in. It may be that some local deformation is taking place to cause the anomaly.

9.4 FURTHER DISCUSSIONS

The general form of residual stresses distribution in the chain links is quite complex, but in the barrel of the chain links, it can roughly be understood as arising from plastic flow in tension and bending under load, Fig. 9.2 (a). Then the tension and some of the bending is removed during unloading (Fig. 9.2 (b)), but without refined analysis, the extent of bending cannot be evaluated. Hence the FE method plays an important role in establishing the residual stress distribution.

The total force and moment operating on any section cut through the chain link (or body) to produce two halves must be zero to satisfy the static equilibrium condition within the link [29]:

$$\int \sigma \, dA = 0$$

$$\int dM = 0$$

It is possible that there are more radical ways of affecting the properties of chains. If one considers load-carrying properties alone rather than, for example, fatigue strength, then one approach would be to make use of a higher tensile strength material by alteration of heat treatment or steel specification. This would, however, almost inevitably result in a reduction in the elongation of the chain at fracture and would not therefore be an acceptable solution. An approach that has been referred to (Chapter 2) is to make use of differential tempering so that the crowns are harder than the barrels. This is done by an additional tempering operation with a specially designed coil so that the eddy currents are produced principally in the barrels. During tensile elongation, the crowns remain resistant to plastic deformation so that the bending moment applied to the barrel is much reduced. The stress state in the barrel then approximates to uniform tension, and there is no region of compression as in the standard chain. The extension of the chain then comes mainly from the barrels: the load-carrying capacity is increased because the barrel material, being entirely in tension, is more effectively used.

Whilst differential heat treatment is undoubtedly an effective method of raising the chain's load-carrying capacity, calibration is still employed to raise the effective elastic limit. The question of the effect of differential tempering on the residual stress field and on subsequent fatigue behaviour is unclear.

A preforming stage to modify the chain shape has already been referred to, namely, the rolling of flats on the 22 mm round bar before forming "oval" links. One can, of course, envisage more extensive preforming, carried out with the objective of raising the resistance to bending in

the crown, in much the same was as in the use of differential heat treatment, or possibly giving the barrel section a reduced resistance to bending. Some work has indicated that this approach might be effective [43], but it is questionable whether the extra manufacturing costs could be justified by the consequent improvement in properties.

Although fatigue testing is specified for mining chain, it is not clear to what extent it is actually relevant, since most mining chain is withdrawn from service because of wear due to rubbing. For hoist chain fatigue properties are probably more relevant. However, if fatigue strength is important, and the chain is used with its surface unchanged from that produced by heat treatment in air, then the surface decarburization thereby produced means that the advantages of high tensile strength in improving fatigue strength are largely. lost, In these circumstances, calibration remains the only way of making use of the higher tensile strength, since higher residual compressive stresses can be produced in the higher strength material. In addition, as shown by Foly et al [24,25], removal of the decarburized surface could additionally be used as a means of raising the fatigue strength.

CHAPTER 10

CONCLUSIONS AND SUGGESTIONS FOR FURTHER WORK

10.1 CONCLUSIONS

This work has dealt with the application of the finite element (FE) method to chains in order to determine the effect of the link shape on both the stress under load (total stresses) and residual stresses and to enable informed decisions to be made regarding the selection of link shape.   The research was applied to 7 mm lifting chain and to 19 mm and 22 mm mining chain, the diameter referring to the diameter of the circular section rod from which the link is manufactured. In the case of the 19 mm links, three geometries were examined: straight sided, pinched (eight shape) and elliptical. The 22 mm rod had flats rolled on it before manufacture of the chain: it is referred to as oval-link. The FE work was supported by the following practical methods of stress determination: strain gauge (for stresses and under load and residual stresses): x-ray and neutron diffraction (residual stresses). Static tensile and fatigue testing (7 mm lifting chain) was also carried out.

1

Calibration of the 7 mm lifting chain significantly improved the fatigue performance.   The improvement is ascribed to the presence of compressive residual stresses at the position of formation of fatigue cracks, which changes the mean stress in the fatigue cycle. The effect was reproduced with plain specimens, with a surface comparable to the chains', under direct stress loading.   Statistical investigation showed that the fatigue fracture positions were affected by increase in calibration load and also by batch variation.

2

X-ray measurements of the residual stresses in 7 mm lifting chain and 19 mm mining chain after calibration revealed the presence of compressive residual stresses in the surface.   Residual stresses

within the volume of the 19 mm mining chain were measured by neutron diffraction and found to be in good agreement with the FE results.

3

Strain gauge measurements of the strains in the 19 mm mining chain (3 link geometries) and the oval-link under load- both for the initial elastic strain and after yielding - were in good agreement with the FE work. The residual stresses measured by the strain gauges were predominantly compressive. There are two positions on the outside of the elliptical and oval-links where tensile residual stresses were indicated, in contradiction of the FE work. This has little bearing on the chain's fatigue performance, however, since the stresses under load at these locations are compressive.

4

Most of the FE work was carried out with three-dimensional elements. Comparable results could, however, be obtained with some reduction in computing time by the use of beam elements. Realistic representation of the loading is necessary: point loading between the links is inadequate.

5

Comparable results were obtained using two-dimensional contact analysis of the 19 mm standard mining and 7 mm lifting chains (Chapter 7). Furthermore, increase in calibration load improved the surface residual stresses, that is, they became more compressive. The information on the contact area and pressure envelope was used to model the contact in the three-dimensional stress analysis.

6

A full three-dimensional stress analysis of all the above mentioned various link geometries were carried out. Overall, the standard 19 mm mining chain link geoemtry is the optimum shape as far as the total and residual stresses are concerned (Chapter 8). The stresses (total

and residual) in this link geometry tend to lie between the eight shape and elliptical link geometries. The residual stresses are all compressive except for the eight shape link which has tensile stresses on the inside of the barrel centre, confirmed by the strain gauge work. For a given nominal cross-sectional area, the oval-link geometry is advantageous in contrast with the circular cross-sectional link geometry considering total stresses only, while considering residual stresses the situation is reversed (Section 8.3.2).

In the 19 mm standard chain link, a change in barrel length (pitch) and inside diameter (inside width) at the crown has a significant effect on the total and residual stresses at the chain link surfaces. For a given barrel length, the narrowest link is the optimum shape as long as the the inside diameter at the crown is larger than the chain link's own diameter with respect to both total and residual stresses. On the other hand, for a given inside radius at the crown, the total stresses are decreased by an increase in barrel length and, in the case of the residual stresses, the situation is not clear cut, that is, the compressive residual stresses are larger in some regions than the others.

Whether a link geometry is an optimum shape or not depends on the state of the service stresses (combination of total and residual stresses). This implies that for calibrated and non-calibrated chain links the optimum link shape would be different. All the stresses obtained from the FE work were validated by the use of strain gauge technique. Some discrepancy between the two sets of results is to be expected because elastic unloading was assumed in the FE work (that is, the Bauschinger effect was neglected). This should result in an over-estimate of the residual stresses.

10.2 SUGGESTIONS FOR FURTHER WORK

The study reported here has shown that using the finite element method in conjunction with the experimental total and residual stress measurement techniques can provide valuable information about the effect of link shape on chain performance [136,137,138]. The experimental techniques have demonstrated the validitiy of the results predicted by FE analysis. The research can be extended in a number of ways:

1

The fatigue limits of the 7 mm lifting chain may be determined at various calibration loads with further testing of different batches to examine the effect of batch variations in the fatigue testing results. Better knowledge of the fatigue life statistics is needed to be able to predict the effect of chain length (the number of links) on fatigue life.

2

Further x-ray measurements of residual stresses are required to clarify the effect of increasing calibration load on the residual stresses in both grades of chains. In the neutron diffraction work, finer sampling volumes should be taken in the regions of steep stress gradients to establish the residual stress pattern more accurately within the centre of the 19 mm mining chain as well as extending the measurement to other critical sections such as: transition and crown regions.

3

Further work is required to establish the residual stress pattern thoroughly by using extra sampling points in the strain gauge work and further testing of the chain material specimens to complete the

stress-strain curve. The forming of the non-standard links needs to be improved so that they conform more accurately to the assumed model.

4

A complete three-dimensional contact analysis of the chains should be carried out to achieve the best solution in conjunction with other complicated alternatve geometries [47,48] not considered here.

5

Finite element analysis in conjunction with fracture mechanics should be applied to estimate the flaw size that the inspection techniques applied to chains should be capable of detecting [139].

6

In service, chains can inevitably undergo impulsive or shock loading which can cause a sudden failure of the chain. This problem was approached in the appropriate standards by the introduction of energy absorption factor (Appendix A) which is an empirical method and a through understanding of the problem may be achieved by the use of FE.

7

More radical changes in link shape may be considered, such as: variable cross-sectional area at different parts of the link geometry (e.g., narrower at the centre and thicker at the crown) perhaps coupled with differential heat treatment which is already in use in the chain industry. The FE can be used to take up this task.

8

Further work is required to clarify the anomaly ocurring in the strain gauge work for determination of residual stresses in the standard, eight shape and elliptical geometries (at the outside transition). FE residual stress determination should be extended to cater for the Bauchinger effect on unloading.

Butt welding	**Flash welding**
Characteristics	
short weld time clean process low material consumption	longer weld time dirty process high material consumption
Chain bending requirements	
drawn annealed wire very good surface finish close bending tolerances notched weld ends	hot rolled wire cleaned rolled finish wider bending tolerances acceptable plain weld ends
Quality consistency with wider chain bending tolerances	
poorer as operation mechanically controlled	better as operation process regulated
Application range	
up to 20 mm dia. approx.	from approx. 13 mm dia. up

APPENDIX A

ENERGY ABSORPTION FACTOR

ENERGY ABSORPTION FACTOR
_____

A chain normally breaks for one of the two reasons, either the application of a static load equal to, or in excess of, the breaking load, or the sudden application of a load ('snatch' or 'shock' loading) which in the absence of shock would not have caused breakage. Static over-loading is a less frequent cause of breakage and the specifications guards against breakage due to this cause by laying down a minimum actual breaking load and the adoption of an appropriate safe working load. The ability of a link to withstand 'shock' loading is dependent on the amount of energy which a chain absorbs and is a function of the product of load and extension: any increase in either, accepted by the chains, will denote an increase in the energy which the chain is capable of absorbing. This is called energy absorption factor and expressed in the appropriate standards in terms of constant X d^2 (d being the diameter of the bar of which the chain is made), [140]. This is employed for chains made from mild steel.

For the lifting chains, the total ultimate elongation shall not be less than 17% and 10 % for non-calibrated and calibrated chains respectively [10,11,12,13,14,15]. In the case of mining chain it is 12 % [19].

For comparison purposes all the results are based on a test length of 36 inches. The equivalent extension is the extension measured, multiplied by 36 and divided by the unstretched test length in inches. The equivalent extension - irrespective of the size of the chain - shall not be less than 3.5 inches [140].

For the 7 mm lifting chain tested in Chapter 3 the following applies:

Before test   length/link = 4.315/5 = .863   inches

After test   length/link = 3.131/3 = 1.044   inches

Equivalent extension = 36*(1.044-.863)/.863 = 7.550 in > 3.5 in   [140]

The product obtained by multiplying the equivalent extension in inches

by the breaking load in tons shall be not less than that specified in

BS4114, i.e. 320 d^2 tons in, where d is the size of the chain in

inches (diameter of the rod used in the chain's manufacture).

The breaking load was 68.5 kN, so the energy absorption factor when

uncalibrated is (1 tonf = 9964 N):

68.5*1000*7.55/9964 = 51.9 ton in > 320 d^2 = 24.3 ton in   [140]

Also percentage elongation for the non-calibrated chain is

(1.044-.863)/.863 = 21 %   > 17 %   [10,11,12,13,14,15]

The requirements of the standard are thus met by the uncalibrated

chain.

To examine whether the calibrated chain meets the requirements of

the standard, let us consider calibration loads of 38.5 and 50 kN.

a) cl=38.8

From Fig. 3.27 the extension is .27 on the scale (.27*50/15 = .9 mm)

i.e.   .9*100/25.4*4.315 = .82 %

b) cl=50 kN

From Fig 3.27 the extension is .175 on the scale (1.75*50/15= 5.83 mm)

i.e. 5.83*100/25.4*4.315 = 5.32 %

The remaining extension is therefore   (21 - 5.32)= 15.68 %   > 10 %

Hence the requirement was satisfied.

c) Calculation of the maximum calibration load

If x is the maximum calibration load and l(x) the corresponding extension then

[5*(1.044) – l(x)]/l(x) = .1

l(x) = 4.745 in

Δl(x) = 4.745 – 5*.863 = .430 in   (i.e. 3.28 on the scale)

From Fig 3.27 maximum calibration load which can be applied is 56 kN. Hence, cl=50 kN used in Chapter 3 is well below the maximum calibration load.
